# Preface

---

Veterinary toxicology is a very complex, yet fascinating, subject as it deals with a wide variety of poisons of plant, chemical and animal origins. Presently, synthetic compounds constitute the largest number of chemicals that are frequently encountered in animal poisonings. The subject of veterinary toxicology is complicated greatly by the wide variations in responses of domestic, aquatic, wild and zoo species to toxicants. Of course, there are many other factors that can be involved in the overall toxicity of a chemical. In the last few decades, veterinary toxicologists have faced the enormous task of dealing with a flood of new farm chemicals and household products. Understanding the complete profile (especially mechanisms of toxicity) of each toxicant is the biggest challenge for today's veterinary toxicologists.

By the turn of the 21st century, we began to face new problems. For example, during the incident of September 11, 2001, a large number of pets died from the collapse of the World Trade Center in New York City, while the surviving ones still suffer from a variety of illnesses (Ground Zero Illnesses) caused by the dust, debris and toxic chemicals. In 2005, two major hurricanes (Katrina and Rita) devastated the lives of so many animals in the Gulf Coast states of Louisiana and Mississippi. Thousands of animals died, while a large number of others suffered from intoxication with high levels of metals, pesticides, algal toxins and many other unidentified toxic substances.

Since the publication of the first edition of *Veterinary Toxicology: Basic and Clinical Principles* in March 2007, several man-made and natural disasters have occurred, which have devastated the lives of humans and animals alike in many parts of the world. For the interest of readers, a few such incidents are mentioned here in brief. In early 2007, melamine became a household name for pet owners in the U.S. because many dogs and cats died

from renal failure, while hundreds were sickened due to the consumption of food tainted with melamine and other co-contaminants (cyanuric acid, ammeline and ammeline) imported from China. Regulatory action of the U.S. Food and Drug Administration led to the recall of more than 150 brands of pet food. Similar recalls occurred in Asia and South Africa. One year later, more than 300,000 children were found to be affected in China by melamine-adulterated infant formula. Over 50,000 children were hospitalized and at least a dozen of them died. Children were also reported to be sick from melamine in other parts of Asia, including Singapore, Taiwan and Vietnam. In 2008, just prior to an international polo event in Florida, 21 horses from a Brazilian team died acutely due to an overdose of selenium. In 2010, the Deepwater Horizon oil rig explosion killed 11 workers. The subsequent oil spill in the Gulf of Mexico caused deaths or affected the lives of millions of birds, fish and other species including dolphins, costing billions of dollars. In the recent past, massive flooding in Australia, Pakistan, the U.S., and many other parts of the world has caused havoc for animals because of drowning, snake bite and toxic debris exposure. On March 11, 2011, a severe earthquake and subsequent tsunami that struck Japan led to the deaths of thousands of humans and animals. As a result of the tsunami and aftershocks, the Fukushima Daiichi Nuclear Power Plant was severely damaged. Deaths of many companion animals occurred within a few days from excess radiation exposure. A large number of surviving abandoned livestock, horses and companion animals in the danger zone continue to suffer from cancer and other radiation-related complications. One month later, a record number of tornadoes (>365) hit the U.S. in various states within a span of less than a month. Two killer tornadoes, which hit the southern part of the U.S., one in Tuscaloosa, Alabama, and the

other in Joplin, Missouri, devastated the lives of humans and animals alike.

It appears that from time to time, unusual toxicological problems are encountered on a small or large scale, and that trend will most likely continue in the future. Around the world, animals and humans are living in a more polluted environment today than ever before. Many of the toxicological problems are global, while others are regional. Unfortunately, the availability of antidotes for common poisons is still obscure and often delayed. Thus, veterinary toxicologists have a tremendous task ahead to face the new challenges of the 21st century.

The first edition of *Veterinary Toxicology: Basic and Clinical Principles* was prepared to offer a comprehensive resource to veterinary toxicologists, students, teachers, clinicians, nutritionists, animal health scientists and environmentalists. The second edition maintains the same temper, yet is more student/teacher friendly and targeted primarily for the classroom. The existing chapters have been updated, while many new chapters (some pertinent to European problems) are added, identifying new problems. The entire volume is organized in 18 sections, with a total of 104 chapters, to offer a standalone chapter on as many topics as possible. The book is heavily focused on target organ toxicity and poisons of various types and classes. Several chapters provide the latest information on problems related to industrial, environmental, aquatic, marine and zoo toxins. This volume extensively covers chapters on poisonous plants, mycotoxins and feed and water contaminants. A significant portion of the book is devoted to diagnostic toxicology that entails sample submission, basic concepts

of analytical toxicology, toxicoproteomics and microscopic analysis of feed. Finally, the book concludes with an emphasis on prevention and therapeutic measures of common poisonings.

In the last couple of years, veterinary toxicologists from many parts of the world have expressed the need for a 2nd edition of *Veterinary Toxicology: Basic and Clinical Principles*, a standard book that can provide detailed coverage of the basic and clinical principles of veterinary toxicology. In light of these basic objectives and the current world situation, the book is revised accordingly. It addresses both global as well as regional toxicological problems, and adequately offers practical solutions. On every major topic, a standalone chapter is provided that is further enriched by major references for further reading. The chapters of this book are contributed by the most qualified and well-experienced authors who are considered authorities in their respective areas of veterinary toxicology. The overarching goals of this volume are achieved by the hard work of all authors. This book represents a collective wisdom of more than one hundred authors, and offers a unique text/reference source for those involved in veterinary medicine in general and toxicology in particular.

Finally, the editor is deeply indebted to all authors for their sincere and dedicated contributions to this book. A special thanks to Mrs. Robin B. Doss and Ms. Michelle A. Lasher for their technical assistance in the checking of references. The editor and the authors offer their sincere thanks to the publishing editors (Mary Preap and Kristine Jones) and the project manager, Julia Haynes at Academic Press/Elsevier for their vital input in the preparation of this book.

# Veterinary toxicology: a historical perspective

Frederick W. Oehme

What's this about veterinary toxicology? Where did it come from? How did it evolve to get that way? What's its current focus and where is it going? These are all stories worth telling. Let's start at the beginning...

Animals have traditionally been "second class citizens" to humans in the hierarchy of life on this planet. They have been used as food sources, to perform labor, for sport, and in recent centuries to serve as guardians of property. Of late some species have become companions to humans and given pleasure to their owners. Their economic value increasingly caused some humans to address the health needs of animals in their care first by addressing obvious concerns, then by applying common sense and with the advent of "therapies" to use counter-measures to "heal" the stricken animal.

In the beginning folk medicine was employed to deal with sufferings produced by "spirits" or other mysterious agents. Equally vague efforts to deal with these little understood illnesses evolved into ritualistic "medicine"; the application of rituals, incantations, charms, liquids, plants and herbs. Studies of how illnesses work and categorizing them into specific etiologic agents produced medical diagnoses, and then disciplined further into pathophysiology and therapeutics for effective therapy. Individuals with the interests and experiences in medicinal chemistry observed and recorded the effects and values of such applied information.

With the use and application of natural and synthetic chemicals to reverse the ill-effects from challenged body functions, pharmacology grew into its own specialty dealing with using these same compounds for therapeutic purposes. With even more sophistication, recognition of the numerous dangerous effects from these products called for a clearer definition and understanding of what

separated a "safe" medicinal from one that caused more pain and danger than the illness being treated; i.e., the thesis of "dose is everything" was born... and with it and its confounding parameters, toxicology was born!

And what a prodigious science that birth produced! Spurred on by the industrial revolution, urbanization and "better living through chemistry," the unfortunate ill-effects of "too much" became obvious. Instances of chemical misuse, finding chemicals in unexpected locales, and the lack of the knowledge needed to deal with environmental, human and animal toxic misadventures spurred public outcries. Government actions followed, but were also led by concerned and inquiring scientists. Their recognition that there is strength and opportunities in bonding together to encourage and share the development of this necessary and energetic science flowed into the growth of international organizations fostering and sponsoring the growth of toxicology in all its important ramifications.

## THE EMERGENCE OF VETERINARY TOXICOLOGY

Increased sophistication of human pathology and forensic medicine stimulated similar developments in veterinary medicine. With the ever-increasing expansion of livestock populations on western ranges, concern developed for the death losses from consumption of poisonous plants. Poor grazing conditions and access to often unrecognized toxic range plants stimulated a wide range of investigations by federally employed as well as

private veterinarians and resulted in large numbers of publications in the 1920s and 1930s to inform livestock owners and reduce losses. With this came the need for clearly identifying what toxic components were present and how they might be effectively treated. Such studies recognized the value of the veterinarian's training and utilized his multifaceted skills in toxicologic studies for clinical evaluations. This was rapidly recognized by industrial institutions and the veterinarian's talents were sought for application to commercial drug trials in laboratory animals. These veterinary scientists wearing the hat of toxicology began expanding their responsibilities to biochemical separations, electron microscopy and studies of the cellular and molecular mechanisms of these chemical actions.

World War II and the extensive use of insecticides for pest control and speculative gas warfare resulted in veterinarians being employed by the armed forces in other experimental animal studies. After the war, these and newer chemicals were widely applied to problems in agriculture. Their use required skilled veterinary supervision and all too quickly veterinary treatment when the misuse of these potent chemicals occurred. Facilities at universities, such as Texas A & M, and at governmental research institutions, such as the Poisonous Plant Research Laboratory at Logan, Utah, focused efforts on the growing hazards and clinical problems resulting in domestic animals. The growth of the pesticide field, coupled with the intensive land use encroaching on plant and animal habitat, required increasing chemical and biological knowledge to understand and identify the disease processes involved.

Veterinary pathologists, such as C.C. Morrill, W.L. Sippel, K. McEntee and P. Olafson, became increasingly interested in the toxic problems now being seen in expanding numbers. J.L. Shupe concerned himself with detailed studies of fluorine intoxication associated with industrial pollution problems. Veterinary pharmacologists began to investigate specific toxicants and their effects on domestic animals; W.G. Huber studied toxic effects of chemotherapeutic agents and antiseptics; R.P. Link identified dicumarol as the anti-clotting factor in sweet clover poisoning and spoke out warning against insecticide poisonings; P.B. Hammond investigated heavy metal toxicities with particular interests in utilizing chelating agents to treat lead poisoning; O.H. Muth studied trace minerals and their interactions in animal intoxications; R.D. Radeleff worked extensively with insecticides and their harmful effects in domestic animals; J.S. Palmer worked closely with Radeleff performing similar investigations on herbicide and pesticide toxins; W. Binns and J.W. Dollahite studied the pathology and biochemistry of numerous poisonous plant intoxications in livestock. Information describing the specific pathology and biochemistry produced by the

increasingly recognized number of xenobiotics and naturally occurring materials were coupled with the veterinary experiences discovered in diagnosing clinical cases and effectively providing treatment.

By the mid-1950s, toxicology was a highly active area of veterinary medicine. Biochemical and molecular interactions were discussed and the tools of other disciplines were brought to focus upon the problems of domestic animal poisonings. With it, a new breed of veterinarian emerged. The developing veterinary toxicologist had to understand physiology and pathology, but equally important he had to be a chemist with wide knowledge of separative and quantitative instrumental techniques. Professional judgment of clinical episodes and a working knowledge of metabolic and excretory processes were needed. He had to become intimately familiar with pharmacology and the molecular action of a wide variety of chemicals. Understanding treatments to be administered for specific intoxications was necessary. Finally, he had to logically and scientifically put into perspective the often confusing and confounding assortment of signs, lesions and analytical results to reach rational interpretations and conclusions for the numerous problems being solved. Since increasing knowledge was being sought, this well-grounded veterinarian had also to be able to conduct significant independent research in well-equipped facilities. More and more veterinarians now were conducting toxicological research investigations as their primary mission.

## PROFESSIONAL ORGANIZATION AND ACADEMIC RECOGNITION OF VETERINARY TOXICOLOGY

In the presence of this increasing need and professional situation, a small group of veterinarians specializing in toxicology united to focus attention on the needs of veterinary toxicology and to assist the progress and growth of this discipline. The formation of the American College of Veterinary Toxicologists (ACVT) in 1958 was the beginning of formal development and recognition of veterinary toxicology. At a meeting in Salt Lake City, Utah, on January 15, 1958, the ACVT was formed by 11 veterinarians stimulated by and engaged in toxicology. The organizing committee consisted of Drs. Chapman, Christofferson, Furgeson, Harris, Hayden, Holmes, Jones, Phelps, Shupe, Spencer and Vinsel. The group's objectives were: "To further the educational and scientific progress in veterinary toxicology and to encourage education, training and research in veterinary toxicology; To establish standards of training and experience for... specialists in veterinary toxicology; To further

recognition of such qualified specialists...; To arrange meetings to promote discussion and interchange of ideas in the following fields of veterinary toxicology: teaching, research and development, diagnosis, nomenclature, public health...; To provide all possible aid and assistance to its members by the interchange of ideas and scientific information; To review manuscripts...; To review published material and keep a file on such reviews...; To accumulate and disseminate information in the field of veterinary toxicology...; To encourage adoption...of uniform clinical and laboratory reporting methods...; To suggest or direct basic research in those areas of deficient knowledge..." (Constitution, 1958).

By 1968 the ACVT grew to over 100 Fellows and Associate Fellows. It had worked efficiently and had stimulated national and international recognition of veterinary toxicology as a progressive and dynamic specialty.

This vitality was further stimulated in 1964 by the New York Academy of Sciences publishing a volume devoted to veterinary toxicology based on the proceedings of an international meeting held in New York City (Gabriel, 1964). This symposium provided basic information on the energetic activities in veterinary toxicology at that time and had the effect of stimulating further growth and multidisciplinary efforts in the field.

The increasing demand for specialized training in veterinary toxicology also encouraged academic training programs. Early efforts were established in universities at Cornell, Utah State, Iowa State, Florida, Kansas State and others. This proliferation has continued with training centers established in other universities and institutions, in veterinary diagnostic laboratories and including research training in molecular and genomic toxicology investigations throughout the United States and around the globe. These early centers and their offsprings have fostered the talents to understand and deal with numerous environmental and clinical problems in veterinary medicine.

Academic recognition of veterinary toxicology was initiated with the American Board of Veterinary Toxicology (ABVT) being formally recognized by the American Veterinary Medical Association (AVMA) in mid-1960. Largely through the efforts of R.D. Radeleff during his term as president of the ACVT, an application for approval of the specialty was accepted by the AVMA Council on Specialty Organizations. A Certifying Board of W. Binns, J.W. Dollahite and R.D. Radeleff was designated to conduct the first examination leading to Diplomate status in the ABVT. Specific training and experience requirements were established for applicants and approval of each applicant's credentials was necessary before the candidate was admitted to the examination. Satisfactory completion of a comprehensive written examination was the final requirement for certification and the privilege of adding "DABVT" behind the

successful candidate's name. The first ABVT certifying examination was held in July 1967 in Dallas, Texas. The five successful candidates joined the three original members of the Certifying Board to form the initial group of certified, i.e., "Boarded," Veterinary Toxicologists (Oehme, 1970).

Since that time, annual certifying examinations of the ABVT have been given associated with the Annual Meeting of the AVMA. This certifying body has continued to set and maintain standards of qualification for veterinary toxicologists, and has complemented the continuing growth of veterinary toxicology experience and knowledge. By 2007 a total of 115 veterinarians have successfully completed the examination challenge and become Diplomates. Their special talents and skills continue to be professionally applied in academia, in industrial roles, as regulatory officials, at poison control centers and within diagnostic laboratories, and in consulting responsibilities throughout the world.

In the years since the discipline's early embryonic period, veterinary toxicology has evolved into a multidisciplinary focus that embraces all of the basic and clinical sciences. Its unique focus is not only the diversity of its embracing activities, but also the many talents and energies of its participants. It harbors a true global theme and is proud of its recognition and membership in "the only medical profession licensed for treating more than one animal species."

## PUBLISHED VETERINARY TOXICOLOGY LITERATURE

Individual authors in the past have attempted to summarize the concepts of veterinary toxicology. The most recent is *Veterinary Toxicology: Basic & Clinical Principles*; an encyclopedic documentation of the developments in veterinary toxicology over the past four decades with glimpses into the promises of exciting future growth. In logical and well-organized fashion, the contributors cover the vast and dynamic field of veterinary toxicology.

The tome on "General Principles of Veterinary Toxicology" is by one of the ABVT certified veterinarians from the initial 1967 examination in Dallas. The appropriateness of this contributor being a 40+-year Boarded veterinary toxicologist should not be lost to readers. The intensity and diversity of veterinary contributions to toxicology – pharmacokinetics, testing models, epidemiology, regulatory concerns, the timely heightened awareness of terrorism and the increasing necessity for legal compliance and actions – are documented.

Any toxicology text would be remiss if it did not focus on individual organ systems and their respective

toxicological effects and clinical manifestations. Sections move through each biological system and end with immunotoxicology and the disastrous effect that various chemicals can have by upsetting this balance of nature.

Of more recent origin are the veterinary efforts of exploring nanoparticles, radiation, and the mechanisms and models of investigative carcinogenesis utilizing various animal species. The veterinary toxicologist is foremost in working with such models and evaluating study results. Of additional current importance are the chapters on over-the-counter drug toxicity and the prevalent potential of various drugs of abuse to affect animal health.

The traditional group of toxic elements is intelligently and dramatically discussed in Section V, where metals and micronutrients ranging from aluminum through zinc are laid out in all their toxicity. No group of toxic elements is more historically relevant to toxicology than compounds such as arsenic, copper, fluoride, lead, mercury, selenium, and zinc, and when interspersed with some of the minor minerals, a complete array of metal and mineral animal intoxications is provided in this section.

The original emphasis for development of veterinary toxicology comes to the forefront in the middle of this volume. The organochlorines and the organophosphates/carbamates are extensively reviewed. Rotenone sneaks in, but the more recent toxic developments with pyrethroids, fipronil, imidacloprid, amitraz, and ivermectin and selamectin are prominently presented. The section on rodenticides and avicides, as well as the brief section on herbicides and fungicides, highlight the array of agricultural chemicals that have spurred not only the long-term developments in toxicology but also the environmental impact of widespread use of these groups of compounds.

The environmental areas of veterinary toxicology are discussed by reviewing industrial toxicants and the residual impacts of the biphenyls, dioxins and dibenzofurans. The environmental impact of these and other chemicals found in the environment are highlighted by extensive chapters dealing with their toxicity in birds, an introduction to ecotoxicology, and the distribution of chemicals in the global marine environment through aquatic toxicology, and the adverse effects of cyanobacterial toxins and others affecting marine animals. The extensive information on botulinum neurotoxin and the enterotoxins is not overlooked. Neither are the poisonous and venomous compounds generated by animals in the terrestrial environment. The chapter on "Mare reproductive loss syndrome" presents up-to-date information on this event's disastrous effect on equine breeding stables and the puzzling origin of these problems. An in-depth discussion on chemically induced estrogenicity and phytoestrogens brings readers current with this unique toxic hazard in all animal species including humans.

Section XIV is another expansive discussion of the still important poisonous plant concerns that contribute to

and continue to stimulate the interests and skills of veterinary toxicologists. The groups of important poisonous plants of the USA, Europe, Australia and New Zealand are reviewed, and then specific categories of plant toxins are presented: cyanide; nitrate/nitrite; oxalates; *Datura* and related plants; fescue; mushrooms; cottonseed toxicity; and the *Taxus* alkaloids. All these are common and highly concerning dietary risks for livestock and other animal species existing in the natural environment.

Fungal toxins are grouped under the "Mycotoxins" section where aflatoxins, trichothecenes, zearalenone, fumonisins, ochratoxins/citrinin, slaframine, ergot, and the interestingly and dynamic tremorgenic mycotoxins are nicely presented. These compounds present not only animal hazards, but are also important public health concerns for the dietary contamination of grains and other human food sources. Other dietary contaminants are reviewed in the section dealing with "Feed and water contaminants." Melamine and cyanuric acid, ionophores and nonprotein nitrogen dietary supplements are highlighted. Not to be overlooked, water quality and contaminants of water sources alert diagnosticians to the hazards and often animal-threatening risks involved with these aqueous contaminants.

The concluding sections in this book of facts and knowledge address how current methodology allows confirmation of specific poisonings and the appropriate means by which poisoned animals may be treated and managed. After reviewing the basic concepts of analyses, appropriate sample submission requirements for such procedures, the use of proteomics for diagnostic application, and the application of microscopic analyses of feeds and animal ingesta for toxic components in the diagnostic process are presented. To wrap it all up, a concluding section on therapeutic measures offers recommendations on how to prevent poisonings and, if necessary, what treatments may be applied to treat individual intoxications.

The basic principles of veterinary toxicology have been utilized to understand the mechanisms of toxicology, to relate to the numerous and challenging individual chemical constituents that offer risk and produce injury to animals and indirectly to humans, and to offer current information and recommendations for identifying such problems and specifically managing their animal and public health effects.

## ...AND WHERE WILL VETERINARY TOXICOLOGY GO FROM HERE?

It should be apparent that veterinary toxicology is about everything – from initial concerns of animal illness to specific molecular and genomic impacts in all of society.

The veterinary toxicologist is well equipped and active in identifying the opportunities and challenges presented. The discipline stands increasingly ready to contribute to medical science by utilizing its broad talents to have significant impacts for the health of all animals on this globe.

What's veterinary toxicology all about? The answers are to be found in this second edition and other volumes likely to be available in future years! May you use this forthcoming information and challenges to the benefit of society and science!

# Concepts in veterinary toxicology

Roger O. McClellan

## INTRODUCTION

Toxicology, from the Greek words *toxicon* for poison and *logos* for scientific study, is the study of poisons. Veterinary medicine is that branch of medical science concerned with the diagnosis, treatment and prevention of diseases in animals. The adjective veterinary is derived from latin – *veterinae*, beasts of burden. Obviously, the modern field of veterinary medicine extends beyond the “beasts of burden” to include all the domesticated animal species, both livestock and companion animals, as well as non-domesticated species. Indeed, it has expanded to include non-mammalian species. While the focus of toxicology remains on chemicals, it is generally acknowledged that the study of effects of ionizing radiation is a part of the field or at least a closely related specialty. Pharmacology, from the Greek words *pharma* for drugs and *logos* for scientific study, is a closely related field concerned with the science of drugs: their preparation, properties, effects and uses in the diagnosis, treatment and prevention of disease.

The field of toxicology is very broad, including the identification and characterization of poisons, their physical and chemical properties, their fate in the body and their biological effects. In addition, toxicology is concerned with the treatment of disease conditions caused by poisons. The term toxicant and poison are used interchangeably. A toxicant is a material that when it contacts or enters the body via ingestion, inhalation, dermal contact, or injection interferes with the normal biological processes and causes adverse health effects. The term toxin is used to describe poisons originating from biological processes. The term toxic is used to describe the effects of a poison on biological systems.

Toxicosis is the term used to describe the syndrome of adverse health effects that result from exposure to a toxicant. During the last several decades, increased concern has developed for the effects of long-term low-level exposures to toxicants. With these exposures, adverse health effects, if they occur, may be manifest in a non-specific manner as an increase in the incidence of common diseases in a population.

A wide range of materials are capable of producing toxic effects when exposure occurs at sufficiently high levels. Indeed, with extreme levels of exposure most agents can produce adverse effects. For example, while both water and oxygen are required to sustain life they are toxic when the level of intake is excessive. The nature of the toxic responses depends not only on the toxicant but also the route of exposure, the duration and intensity of the exposure, and the characteristics of the exposed individual, i.e., species, gender, age, pre-existing disease states, nutritional status and prior exposure to the agent or related compounds. The exposure may be brief or prolonged. The response may occur acute or chronic and occur soon after exposure or much later and only after prolonged exposure. The response may be relatively unique to the toxicant, i.e., a specific toxicosis, or distinguishable from common diseases caused by natural processes or exposure to other agents. In many cases, sophisticated statistical methods are required to associate some excess health risk, over and above that caused by other factors, with a particular toxicant exposure. This is especially true today after much progress has been made in controlling exposure to toxic materials.

In this chapter, I first provide a brief historical perspective on the development of veterinary toxicology as a sub-specialty of the veterinary medical profession and

as a specialized area within the general field of toxicology. This is followed by a section on the evolution of veterinary toxicology from an observation-based profession and science to one that places increasing reliance on science developed through experimentation. This includes a discussion of the risk paradigm which has become an integral part of toxicology in recent decades. In the next section, I offer several related paradigms for acquiring, organizing and using knowledge in veterinary toxicology so as to maximize its potential impact. Next, there is a section on the sources of information that may be obtained either through observation or experimentation. These sources may include studies on the species of interest, i.e., people or some other specific animal species, controlled exposure studies in the species of interest, studies in other species, investigations using tissues and cells and structure–activity analyses. This is followed by a section discussing the design of experimental studies to optimize the interpretation and use of the results. The chapter concludes with a discussion of key toxicologic descriptors and a brief conclusions section.

## HISTORICAL PERSPECTIVE

### Historical events

The father of modern toxicology is generally acknowledged to be Aureolus Philippus Theophrastus Bombastus von Hohenheim (1493–1541), who referred to himself as a Paracelsus, from his belief that his work was beyond the work of Celsus, a first century Roman physician (Pagel, 1958). Paracelsus is credited with the well-known statement – “All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy.” Paracelsus advanced many views that were revolutionary for his time that are now accepted as fundamental concepts for the field of toxicology. In contrast to earlier emphasis on mixtures, he focused on the toxin as a specific primary chemical entity that was toxic. Paracelsus advanced four fundamental concepts:

- 1 Experimentation is required for examining responses to chemicals.
- 2 A distinction should be made between the therapeutic and toxic properties of chemicals.
- 3 The therapeutic and toxic properties are something closely related and distinguishable by dose.
- 4 It is possible to ascertain a degree of specificity for chemicals and their therapeutic or toxic effects.

It is obvious from the foregoing that toxicology and pharmacology are closely related fields of scientific endeavor. Pharmacology is focused on drugs, including

both their effectiveness and safety. Toxicology is concerned with all kinds of chemicals and other agents that may, at some level of exposure, cause adverse health effects. As will be noted at several places in this chapter, toxicology is increasingly concerned with low-level exposures for which the effects, if any are observed, may not be specific to a particular chemical.

Toxicology, in a sense, dates back to the earliest activities of humans. By observation, people came to learn that which could be ingested without harm and, by contrast, the foodstuffs to be avoided because of their harmful properties. They also came to know which animal venoms, plant extracts and other materials could be used for hunting, warfare and assassination. No doubt as animals were domesticated, it became apparent that the human observations and practices could be extended to domestic animals. Unfortunately, domestic animals are not always as astute as people in learning to avoid poisonous plants and other harmful situations. Thus, veterinary practitioners still encounter toxicoses involving animals ingesting poisonous plants.

The history of toxicology has been well documented by several contemporary authors (Milles, 1999; Gallo, 2008; Lane and Borzelleca, 2008). The history of veterinary toxicology has not been as well documented, although it is apparent that veterinary toxicology has been an integral part of veterinary medicine since the earliest time of the profession. Veterinary medicine is a specialized branch of medical science with formal programs of study leading to a professional degree. The history of veterinary medicine has been reviewed by several authors (Smithcors, 1957; Stalheim, 1994; Swabe, 1999; Wilkinson, 2005). The role of veterinary toxicology in the veterinary curriculum is well documented for one of the earliest veterinary medical colleges, that at the Free University of Berlin. Wilsdorf and Graf (1998) provide an account of the development of veterinary toxicology at that university from 1790 to 1945. Oehme (1970) has briefly reviewed the development of veterinary toxicology as a discipline in the United States.

### Textbooks

In the English language, the earliest veterinary toxicology publication I am aware of is a *Synopsis of Veterinary Materia Medica, Therapeutics and Toxicology* (Quitman, 1905) apparently used at Washington State University College of Veterinary Medicine in the early part of the 20th century. I am uncertain of the extent to which this synopsis may be based on a French text by Kaufmann (1901). The earliest English language veterinary toxicology textbook I was able to locate was that authored by an Englishman, Lander (1912). This book was also prepared in a second edition (1926) and a third edition

was prepared by an Irishman, [Nicholson \(1945\)](#). I am uncertain how widely it was used in the United States. The text included four sections; a brief introduction to toxicology followed by sections on classes of toxicants; mineral or inorganic poisons, organic poisons and drugs; and poisonous plants. This last section represented half of the book.

Many early students in veterinary medicine in the United States used textbooks prepared for physicians such as [Kobert \(1897\)](#), *Practical Toxicology for Physicians and Students*. It was also common to use either textbooks in pharmacology or veterinary pharmacology that contained a brief coverage of toxicology. Indeed, few veterinary medical colleges prior to the 1950s had full-time veterinary toxicologists on their faculty. Lectures on toxicology were usually included in courses in pharmacology, pathology and clinical medicine.

The first veterinary toxicology text I personally used was authored by [Garner \(1957\)](#) who was then a Senior Lecturer in Chemical Pathology (Veterinary) at the University of Bristol in the United Kingdom and later Head of the Radiobiology Department at the Agricultural Research Council Field Station, Compton, Berks, UK. The text by [Garner \(1957\)](#) was intended as a successor to the third edition of Lander's *Veterinary Toxicology* ([Nicholson, 1945](#)). A second edition was prepared by [Garner \(1961\)](#) after he became head of the Public Health Section, Radiological Protection Division, UK Atomic Energy Authority, Harwell, Berks, UK. Later, Garner came to the United States where he was initially associated with Colorado State University directing studies of the long-term effects of external radiation on beagle dogs. I recall asking Garner in the early 1970s about the possibility of preparation of a third edition of his *Veterinary Toxicology* text. He indicated that the field of veterinary toxicology had become so broad that it was not readily feasible for a single individual to author a text in veterinary toxicology and he was not interested in "shepherding" a herd of individual chapter authors with specialized knowledge of various aspects of veterinary toxicology.

[Radeleff \(1964\)](#) authored one of the first veterinary toxicology texts published in the United States. A second edition appeared in 1970. This was followed by a text prepared by [Osweiler et al. \(1985\)](#). Several books published in the 1960s became classics on the effects of poisonous plants ([Kingsbury, 1954, 1964](#); [Hulbert and Oehme, 1968](#)). Recent books on poisonous plants have been authored by [Garland and Barr \(1998\)](#), [Burrows and Tyrl \(2006\)](#) and [Knight and Walter \(2001\)](#). [Murphy \(1996\)](#) has authored a field guide to common animal poisons. It is organized by the organ system affected and then by toxicant.

[Osweiler \(1996\)](#) has authored a text focused on toxicology as part of the National Veterinary Medical Series

for Independent Study. It has been widely used by individuals preparing for the National Board Examinations for Veterinary Medical Licensing. [Roder \(2001\)](#) has prepared a text, *Veterinary Toxicology*, as part of a series *The Practical Veterinarian*. [Plumlee \(2004\)](#) has edited *Clinical Veterinary Toxicology* and [Peterson and Talcott \(2006\)](#) have edited two editions of *Small Animal Toxicology*. The present multi-authored text edited by Ramesh Gupta promises to be the most comprehensive text on veterinary toxicology published to date. It is encouraging that it is now appearing as a second edition. A veterinary toxicology text edited by [Chapman and Campbell \(2011\)](#) is in preparation.

There are a number of comprehensive general toxicology texts available today. I will note four that the serious student of toxicology will find useful to have in their reference library. *Casarett and Doull's Toxicology: The Basic Science of Poisons* edited most recently by [Klaassen \(2008\)](#) was first published in 1975 and is now in its seventh edition. As an aside, I had the opportunity to observe first hand Louis Casarett and John Doull planning the first edition of this new textbook as I served with them on the Toxicology Study Section of the National Institute of Health. Unfortunately, Louis Casarett died of cancer before the first edition ([Casarett and Doull, 1975](#)) was completed. I was pleased when John Doull asked me to prepare the chapter on Radiation Toxicology which my colleague, Charles Hobbs, and I did ([Hobbs and McClellan, 1975](#)) and which Louis intended to write. [Hayes \(2008\)](#), *Principles and Methods in Toxicology*, is now in its fifth edition. *Toxicology*, edited by [Marquardt et al. \(1999\)](#), built on an earlier German text by [Marquardt and Schafer \(1994, 2004\)](#). *Biological Concepts and Techniques in Toxicology: An Integrated Approach* edited by Riviere was released in 2006. Serious students will also want to be aware of a multi-volume comprehensive set of toxicology textbooks. The first edition was edited by [Sipes and colleagues \(1997\)](#) and a 14-volume second edition was edited by [McQueen \(2010\)](#). Moreover, there are numerous text and reference books available now covering various sub-specialty areas such as *Inhalation Toxicology*, *Reproductive and Developmental Toxicology* and *Dermal Toxicology*.

Some readers of this text will also be interested in the related field of environmental medicine which has largely developed with a focus on the influence of the environment on human health. Without question, there is a need to integrate veterinary medicine and specifically veterinary toxicology into environmental medicine. A recently released text, *Environmental Medicine* ([Ayres et al., 2010a](#)), includes a lead chapter that details the context for environmental medicine ([Ayres et al., 2010b](#)). That chapter reviews important information on causes of death in low- and middle-income versus high-income populations ([Lopez et al., 2006](#)) and the

role of environmental versus non-environmental factors as contributors to the global burden of disease (Kung *et al.*, 2008). Recognizing that this text edited by Gupta is intended for international readers, the lead chapter in Ayres *et al.* (2010b) serves as a reminder of the wide range of environmental conditions experienced by people around the world. Veterinarians have an important role to play in promoting human health around the world in multiple ways such as by facilitating the production and availability of safe food products of animal origin and aiding in control of infectious agents.

In addition to text and reference books, there are numerous journals published in the field of toxicology that regularly contain articles that relate recent findings in veterinary toxicology. Many clinically oriented veterinary medical journals contain articles on veterinary toxicology. The online search capabilities serving the medical sciences, including toxicology and veterinary toxicology, are expanding at an exponential rate. Of special note are those maintained under the auspices of the National Library of Medicine, MEDLINE and TOXLINE.

## Organizations

A number of professional scientific organizations have been created as the field of toxicology, including veterinary toxicology, has matured. The most noteworthy include the American College of Veterinary Toxicology (ACVT), American Board of Veterinary Toxicology (ABVT), Society of Toxicology (SOT), American Board of Toxicology (ABT), and Academy of Toxicological Sciences (ATS). The ACVT was one of the earliest scientific societies in the field, being founded in 1958. It now exists as the American Academy of Veterinary and Comparative Toxicology. The ACVT was instrumental in fostering the creation of the ABVT and its recognition by the American Veterinary Medical Association (AVMA) as the approved certifying specialty organization for veterinary toxicology. Three well-known veterinary toxicologists, W. Binns, J.W. Dollahite and R. Radeleff, were accepted by the AVMA as Charter Members of the ABVT. They prepared the first certifying ABVT examination which was given in 1967 (see [www.abvt.org](http://www.abvt.org)). I was pleased to be one of six individuals in the first class certified, based on examination, as Diplomates of the ABVT.

The SOT, with the world's largest membership of toxicologists, was organized in 1961 (see [www.sot.org](http://www.sot.org)). Many of the organizers of the SOT were members of the American Society for Pharmacology and Experimental Therapeutics (ASPET) who felt toxicologists needed a "home" of their own. I recall attending an organizational meeting of the SOT held in conjunction with an ASPET meeting at the University of Rochester and the excitement

and enthusiasm of the attendees for creating the SOT. As an aside, it would be a few years before I felt my credentials were sufficient that I could apply for membership in the SOT. The SOT includes a number of specialty sections including the Comparative and Veterinary Specialty Section and Toxicologic and Exploratory Pathology Specialty Section with veterinarians being a majority of the membership of these sections. Veterinarians have played a major role in the SOT from its founding with many serving in leadership roles. Four veterinarians (Perry Gehring, Frederick Oehme, Roger McClellan and James Popp) have served as president of the SOT.

The SOT fostered the creation of the ABT which held its first certifying examination in 1980 (see [www.abtox.org](http://www.abtox.org)). I was pleased to be one of the first class of individuals certified, based on examination, as Diplomates of the ABT.

A third certifying entity, the ATS, which accepts individuals as fellows based on a review of credentials, was created in 1981 (see [www.acadtoxsci.org](http://www.acadtoxsci.org)). Many veterinary toxicologists belong to all of the organizations noted above and some have been certified by one or more of the certifying organizations; the ABVT, ABT and ATS. Of special note, four veterinary toxicologists (Roger McClellan, Charles Capen, Jim Riviere and Bernard Schwetz) have been recognized for their contributions to human health by election to the Institutes of Medicine of the National Academies of Sciences. Veterinary toxicology has made major contributions as it has continued to evolve over the past decades along with the general field of toxicology.

## EVOLUTION OF VETERINARY TOXICOLOGY

### Roots in veterinary medicine and toxicology

The evolution of veterinary toxicology occurred concurrently with evolution of its two roots; the profession of veterinary medicine and the science of toxicology. The veterinary medicine profession was initially focused on domestic animals, particularly those used for food, fiber, transportation and to provide power for agricultural endeavors and transportation. With the growth of more specialized agriculture and production practices, the profession with its linkage to domestic livestock, stimulated growth of veterinary toxicology. Veterinary toxicology in its earliest years had a major focus on poisonous plants and then on antidotes for various toxins. The early part of the 20th century presented a special challenge for veterinary medicine as the use of horses and mules in agriculture decreased in favor of the use of equipment powered by internal combustion engines. During this period of time, there must have been

considerable uncertainty as to the future of the veterinary medical profession.

By the mid-20th century three movements transformed veterinary medicine. The first related to the traditional roots of the profession in animal agriculture and related to the increasing emphasis given to large-scale highly specialized domestic livestock endeavors. The second related to the increased attention given to providing veterinary medical services to a growing population of companion animals including horses, dogs and cats. In both areas the science of veterinary medicine was strengthened as observation-based medical practice was complemented and, ultimately, supplemented by science-based medicine. During this period, veterinary toxicologists began to play an important role in veterinary medical diagnostic laboratories, both in veterinary medical colleges and in state and federal agencies. With the strengthening of the science base of veterinary medicine, including the quality of the science in the veterinary medical curriculum, the third movement, the emergence of the comparative medicine character of veterinary medicine became more apparent and was enhanced (Wilkinson, 2005). These changes in the profession were accompanied by increased involvement of veterinarians in research on the species of traditional concern to the profession, domestic and companion animals (Stahlheim, 1994), and to participation in a broader range of biomedical research activities, involving use of the traditional laboratory animal species, driven largely by concern for human health (Wilkinson, 2005).

### Emergence of science-based toxicology

Toxicology, like veterinary medicine, was also rapidly changing and evolving in the mid-20th century. The previous strong emphasis on field observations was first complemented and then supplemented by experimentation. This, in turn, led to the current strong mechanistic orientation of toxicology. With this shift in toxicology came an increased awareness of the utility of a comparative medicine orientation in research directed primarily toward improving human health (Wilkinson, 2005). With this comparative medicine orientation came increased opportunities for individuals educated in veterinary medicine, including veterinary toxicology, to contribute to general toxicology and biomedical science.

These changes in the veterinary medical profession and the emergence of toxicology as a science came during a period when the public was giving increased attention to the health risks, and its counterpoint-safety, of new technologies and products. World War II resulted in the creation of the Manhattan Project in the U.S. to develop nuclear weapons. Following the war, the Manhattan Project became the Atomic Energy

Commission (AEC) with a broad mission that included peaceful applications of nuclear energy. A series of national and specialized laboratories were created with several having a mandate to understand the effects of external radiation and internally deposited radionuclide. Veterinarians had a key role in many of these laboratories. My career began at one of the major AEC laboratories, the Hanford Laboratories in Richland, WA, where research was conducted on a range of topics including effects of radioactive materials on domestic animals, a research program initially led by the late Leo K. Bustad, who later served as Dean of the College of Veterinary Medicine at Washington State University. The Hanford Laboratories continue today as the Pacific Northwest Laboratories operated by Battelle Memorial Institute. Later I would lead one of the specialized AEC laboratories, the Lovelace Inhalation Toxicology Research Institute (ITRI), which continues today as part of the Lovelace Respiratory Research Institute. The mission of ITRI was to study the health consequences of exposure to radioactive materials and, then later, a broad range of airborne materials including vehicle emissions. The research conducted at Hanford, Lovelace ITRI and in numerous other laboratories with support from the Atomic Energy Commission, which later became the Energy Research and Development Administration, and then soon became the Department of Energy, provided an enormous knowledge base on the health effects of exposure to both external radiation and radionuclides that would be deposited internally. Contrary to the impression gained from many popular media reports, our understanding of the health effects of radiation probably exceeds our knowledge of any other toxicant.

The post-World War II era was also a period of substantial growth of the chemical and pharmaceutical industries, especially in the U.S. and in Europe. This included development of a wide array of new products including many chemicals used in agriculture and from the pharmaceutical industry the development of many new drugs including many widely used in veterinary medicine. The growth of these industries was intertwined with an increase in research and development. This included substantial research to ensure the safe manufacture of products and their safe use. This continued a tradition begun pre-World War II when the major chemical companies such as Dupont, Dow, Union Carbide, Eastman Kodak and others created laboratories that had a strong toxicology orientation. Many veterinarians played a key role in these laboratories. Unfortunately, these laboratories today are much smaller or have even disappeared.

Despite the substantial knowledge base that was being created and used to guide the safe use of chemicals concerns developed. This concern was the focus of Rachael Carson's book *Silent Spring* (Carson, 1962). She

focused on both human health impacts and impacts on the total ecosystem of which people were just a part. Her book was certainly one of the key stimuli to a tidal wave of legislative actions in the United States that focused broadly on the environment with concern for clean air and water; safe food, pharmaceuticals, pesticides, fungicides, rodenticides, and consumer products; and a safe working environment.

The legislative actions and related administrative actions in the 1970s created the U.S. Environmental Protection Agency, the Consumer Product Safety Commission, the National Institute for Occupational Safety and Health, the National Center for Toxicological Research, the National Institute of Environmental Health Sciences and the Cancer Bioassay Program within the National Cancer Institute, which evolved into the National Toxicology Program now administered by the National Institute for Environmental Health Sciences. This was also a period of rapid expansion of research activities in the pharmaceutical, food, chemical and petroleum industries. The major chemical companies working together started in 1976 the not-for-profit Chemical Industry Institute of Toxicology, which now exists as the Hamner Institutes for Health Sciences, to test commodity chemicals, investigate the mechanisms of chemical toxicity and train additional toxicologists. The Food and Drug Administration continued its traditional dual emphasis of ensuring both the efficacy and the safety of drugs and medical devices continued. Increased emphasis was given by the FDA to veterinary drugs and to the potential for veterinary drugs to contaminate meat and milk.

Increasing public concern for safety/risk and the resulting legislation led to the development of increasingly formalized approaches to both safety and risk analysis. This included more clearly defined roles for using the results of toxicological studies, including studies with laboratory animals, to assess the safety, or conversely risk, to humans of the use of pharmaceuticals, other products in commerce, and technologies.

### Toxicology joined to the risk paradigm

As noted earlier, federal legislation passed in the 1970s focused on health impacts of environmental and occupational exposures and led to more formalized approaches to evaluating the risks and safety of various exposures. The risk paradigm built on the long-standing paradigm linking sources to exposure to dose to adverse health outcomes that had guided toxicology from its earliest days (Figure 2.1). I have reviewed elsewhere the development of the risk analysis paradigm (McClellan, 1999, 2010). The development of risk analysis as a specialized area of interdisciplinary science led to the founding of

the Society for Risk Analysis in 1981. The risk analysis paradigm originally proposed by the National Research Council (1983) and used by the USEPA is shown in Figure 2.2. A later report "Science and Judgment in Risk Assessment" (NRC, 1994; McClellan, 1994) and reports from the Risk Commission (1997) reaffirmed use of the risk paradigm which continues to be a cornerstone of activities not just at EPA but in other national and international agencies and in the private sector.

The original key elements of the risk paradigm were: (1) hazard identification, (2) exposure-response assessment, (3) exposure assessment, and (4) risk assessment. The NRC (1994) report emphasized the importance of a fifth element – using the results of the risk analysis to guide future research and, thus, reduce uncertainty in future risk estimates. In addition, I have added a sixth overarching element – risk communication. The hazard identification element has been a source of contention and confusion both with the public and in the scientific community, especially with regard to cancer as I will discuss later.

Hazard is defined as the potential for an agent under some conditions of exposure to cause an adverse effect (NRC, 1983, 1994; McClellan, 1999, 2010). With this definition the level of exposure or dose required to produce an adverse health effect is not considered. An agent may be classified as a hazard irrespective of whether or not the exposure conditions required to elicit adverse effects under experimental conditions are relevant to human situations. The exposure-response assessment involves characterization of this relationship as it may pertain to likely levels of human exposure. The exposure assessment quantifies, either retrospectively or prospectively, the likely duration and intensity of human exposure to the hazardous agent. The risk assessment element brings together information from the other three elements to characterize risk as illustrated in Figure 2.1. Risk is defined as the probability of occurrence of an adverse health effect from exposure to a hazardous agent at a specified duration and intensity of exposure. As an aside, especially in Europe, the word hazard is used as risk has been defined in the United States. Safety is defined as being a condition with a high probability of freedom from any increase in adverse health outcome when the agent is used in a specified manner. Obviously, both safety and risk are relative recognizing that it is not possible to ensure absolute freedom from some small level of risk. As the control of hazards and risks has improved, in part through more and more stringent regulations, scientists and society at large are increasingly faced with the challenge of how low is low enough?

The more formalized risk analysis approaches developed, starting in the 1970s, built on approaches developed earlier for providing guidance for controlling occupational exposures, the intake of contaminants

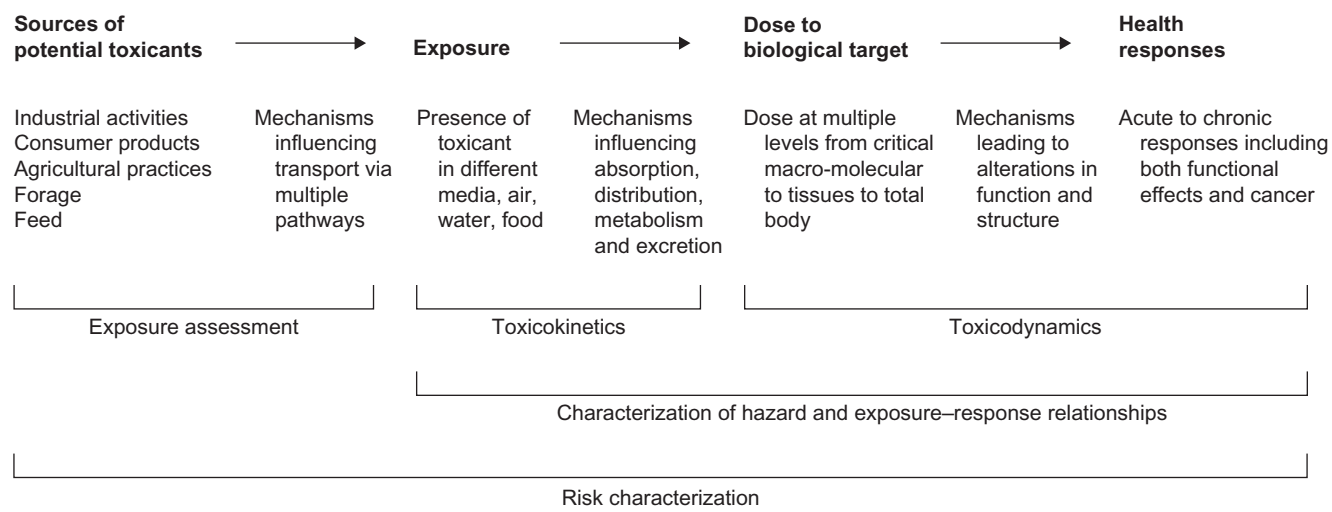

FIGURE 2.1 Critical linkages for integrating information from sources of toxicants to the development of adverse health effects.

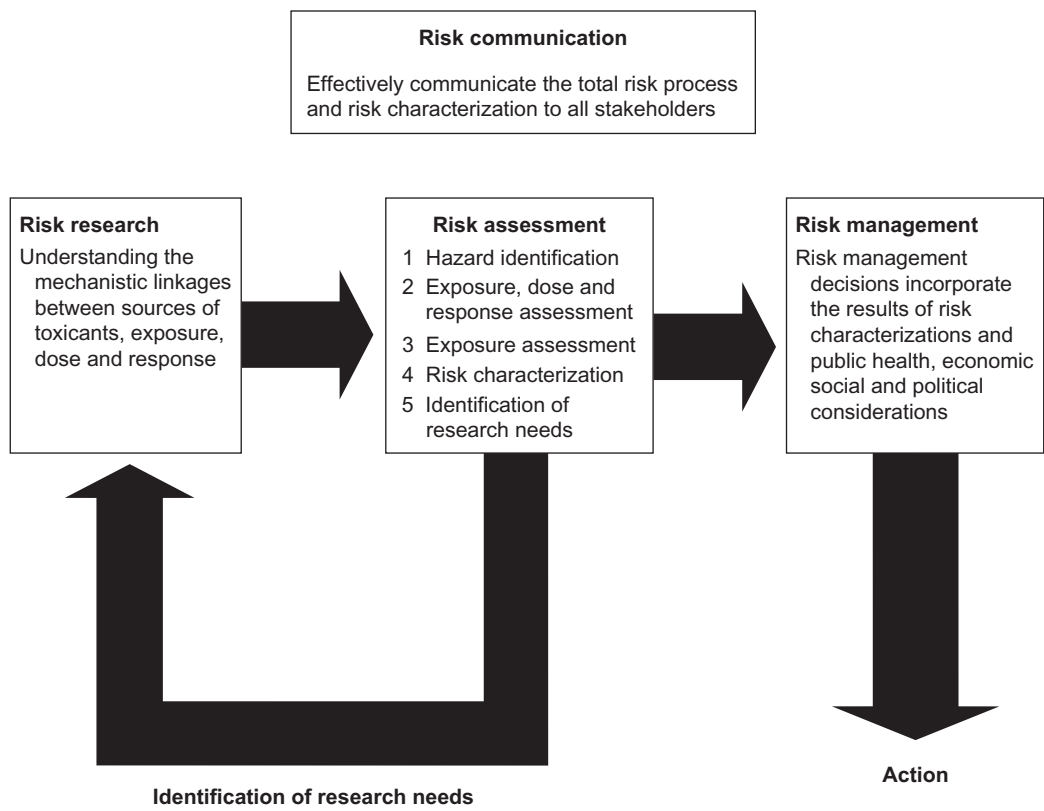

FIGURE 2.2 Risk paradigm for evaluating potential health impacts of a toxicant.

in food and the safety of pharmaceutical agents. Pre-World War II, the primary focus was on adverse health outcomes that caused functional impairment such as decreased respiratory function. As will be discussed later, the issue of carcinogenic responses received limited attention pre-World War II. The approach to developing guidance for the control of toxicants was based

on the assumption that a threshold exists in the exposure (dose)–response relationship – just as discussed by Paracelsus. The threshold exposure–response relationship is shown in Figure 2.3 along with four other relationships; sub-linear, linear, supralinear and a U-shaped or hormetic function. Note that both scales in this schematic rendering are logarithmic.

FIGURE 2.3 Schematic rendering of exposure-response relationships for various toxicants.

Technically, in hormesis there is a beneficial effect at some low level of exposure which decreases with increasing exposure/dose and at yet higher levels adverse effects become apparent. During the last decade, there has been increased discussion of the concept of hormesis in which very low level exposures have positive effects with negative effects observed only at higher exposure levels (Calabrese and Baldwin, 2003; Calabrese and Blain, 2005; Calabrese *et al.*, 2007). The concept of hormesis is well known to veterinarians who are aware that certain agents, such as vitamins and minerals, are essential for life at low concentrations and can produce toxicity with excess intake.

As an aside, there has been ongoing debate for decades as to whether linear exposure-response relationships, especially for cancer, are realistic, i.e., an added level of exposure, regardless of how small, results in a calculable monotonic increase in cancer risk. It has been argued by some that the linear exposure-response model is appropriate for regulatory purposes for assessing cancer risks because every dose of a new agent is added to a background of genetic damage in somatic cells arising from multiple agents and endogenous factors.

In recent years the debate over the nature of the exposure-response relationship has been extended from cancer as an endpoint to non-cancer endpoints. Arguments for the use of linear non-threshold exposure-response relationships for non-cancer endpoints have been advanced by White *et al.* (2009). An alternative view has been advanced by Rhomberg *et al.* (2011a), namely, that linear low-dose extrapolation for non-cancer health effects is the exception, not the rule. Extension of the debate over the nature of the exposure-response relationship to non-cancer endpoints, such as respiratory or cardiovascular morbidity and mortality, has important implications for assessing risks such as from air pollutants like particulate matter and ozone. For

example, the Clean Air Act (CAA, 1970) requires the EPA Administrator to set National Ambient Air Quality Standards (NAAQS) for these pollutants at levels that are protective of public health with an adequate margin of safety. If the exposure-response relationship for the pollutant in question has a threshold then the setting of the standard is relatively straightforward, identify the threshold concentration and set the NAAQS at a lower concentration for a given averaging time and statistical form. If a linear, no threshold, exposure-response relationship is apparent, the question arises as how to determine when the NAAQS is set low enough. McClellan (2011) has addressed that topic in a recent paper drawing on the guidance of Supreme Court Justice Stephen Breyer in the legal case of *Whitman v. American Trucking Associations* (2001). McClellan has emphasized the importance of “distinguishing between the science that informs the setting of the standard and the policy judgments inherent in selecting the standard”.

The early development of threshold limit values (TLVs) for control of occupational exposures by the American Conference of Governmental Industrial Hygienists, organized in 1938, assumed the existence of thresholds in exposure-response relationships. The initial data used in establishing TLVs were provided primarily by opportunistic studies of occupationally exposed human populations. In the absence of human data, data from controlled exposure studies in laboratory animals were used. This necessitated the use of safety factors to account for inter-individual variability, inter-species extrapolation, and duration of the study as will be discussed later. The original safety factors were formally proposed by Lehman and Fitzhugh (1954) of the Food and Drug Administration. In 1970, the USEPA was organized and began using the same factors. However, the EPA identifies them as uncertainty factors apparently out of a desire to avoid use of the potentially contentious word – safety.

Post-World War II increased public concern developed for the occurrence of cancer. This was stimulated by multiple factors. Extensive research conducted during and after the war on the effects of both external ionizing radiation and internally deposited radionuclides emphasized the importance of cancer as a radiation-induced disease. Concern for radiation-induced cancer was further heightened when the intensive follow-up of Japanese A-bomb survivors revealed an increase first in hematopoietic neoplasms and later in solid cancers. These findings soon led to abandoning a threshold approach to evaluating radiation risks in favor of using a probabilistic approach to assess the health risks of using radiation devices in space and nuclear power. The probabilistic approach using the linear exposure-response model discussed earlier was convenient to use because it could be readily applied to assessing the

risks to individuals or populations. My first experience with probabilistic risk assessment came in 1965 when I was on a temporary assignment with what was then the U.S. Atomic Energy Commission (AEC). I worked with a joint AEC–National Aeronautics and Space Administration Committee assessing potential human cancer risks of accidents involved with the launch of space craft containing plutonium-238-fueled thermal electric power systems.

Another factor influencing public concern was the increasing incidence of total cancers being observed in all of the economically developed countries including the U.S. driven largely by lung cancer. It is now well known that the increase in lung cancer, first observed in men and later in women, was largely related to cigarette smoking. Rachael Carson's book also created concern for exposure to man-made chemicals contributing to the increasing incidence of cancer and encouraged the view that somehow man-made chemicals were different than chemicals of natural origin. It is now known that this is not the case (Gold *et al.*, 2003). Ironically, some major commodity chemicals such as formaldehyde are normal constituents of mammals.

The experience with radiation soon resulted in its use as a proto-typical carcinogen in developing approaches to risk analysis and risk regulation. Albert (1994) documented the development of the USEPA's approach to assessing cancer risks. Key assumptions in the approach were: (1) cancer-causing chemical agents acted like radiation in causing cancer; (2) there was a linear relationship between exposure (dose) and increased risk of cancer extending to the lowest levels of exposure; (3) agents causing cancer in laboratory animals could be viewed as also causing cancer in people; and (4) exposure–response relationships could be extrapolated between species by considering differences, body weight and surface area, i.e., metabolic activity. These assumptions were viewed as default options to be used in the absence of specific scientific data to the contrary (McClellan, 1994, 1999, 2003; NRC, 1994).

In response to public concern for chemicals causing cancer, the International Agency for Research on Cancer (IARC), a part of the World Health Organization, was organized in Lyon, France, under the leadership of John Higginson to develop an international research program to study cancer. Higginson's deputy, Lorenzo Tomatis, provided leadership for creating a program to classify agents or occupations as to their carcinogenic potential with the results published in a series of monographs (IARC, 1972). The view was that if cancer-causing chemicals or other agents, such as radiation, or workplace conditions involving exposure to chemicals or other agents causing cancer could be identified, then these could be controlled and the occurrence of cancer in people reduced. The IARC carcinogen classification

scheme considers human, laboratory animal and supporting data to classify agents or workplace conditions as (1) carcinogenic to humans, (2) probably carcinogenic to humans, (3) possibly carcinogenic to humans, (4) not likely to be carcinogenic to humans, or (5) not classified as carcinogenic. The IARC classification is strictly hazard oriented; it does not formally evaluate the potency of these agents for causing cancer at a specific level of exposure.

The USEPA, the National Toxicology Program (NTP) and other organizations have developed similar carcinogen classification schemes (EPA, 1986, 2005a,b; NTP, 2005). In recent years, IARC (1991) has made provision for increased use of mechanistic data in classifying chemicals as human carcinogens. Both the EPA and NTP now also give increased emphasis to the use of mechanistic data in classifying chemicals as carcinogens (EPA, 2005a,b) unlike IARC and the NTP, the EPA does develop estimates of cancer causing potency for some agents classified as having cancer-causing potential. This in turn, using measurements or estimates of exposure, provides the basis for calculating lifetime cancer risks for individuals or populations.

It should be apparent that the classification of a given chemical or agent as to its cancer causing potential is insufficient for characterizing cancer risk since the hazard-based classification does not include an estimate of the agent's potency. The USEPA has estimated the carcinogenic potency for a number of chemicals. The results are usually related as the concentration of a chemical in water or air that will result in a calculated one in a million probability of cancer occurring above the background incidence (EPA/IRIS, 2011). In viewing such estimates it is useful to recall that in developed countries of the world with long-lived populations, about one third of the population will be diagnosed with cancer during their lifetime and one fourth will die with a cancer. To estimate the cancer risk for any agent and exposure situation, it is also necessary to estimate the exposure to the agent, both as to intensity, i.e., concentration, and duration. In short, risk is a product of exposure and the potency of the agent for causing the effect.

There has been a tendency for regulatory agencies, such as the USEPA, to use their experience with classifying chemicals as to their carcinogenic potential as a template for also classifying chemicals as to their potential for producing other non-cancer hazards. Thus, there has been a trend toward classifying chemicals as to their potential hazard for causing different health outcomes and labeling them as such, i.e., neurotoxins, reproductive toxins, hepatic toxins, etc. Indeed, some even broader classifications have emerged, i.e., endocrine disrupting chemicals. In my view, this short-hand approach to identifying and classifying hazardous agents as to their potential to cause cancer or other effects is often

confusing to the public. In my opinion, the labeling approach has contributed to both radiation phobia and chemical phobia and sometimes irrational actions. It certainly flies in the face of the fact that for many chemicals the admonishment of Paracelsus that “the dose makes the poison” remains true for many chemicals. For numerous chemicals, even when toxic effects are apparent at high doses, these same adverse effects are no longer manifest at sufficiently low doses. Gold *et al.* (2003) has discussed the challenge of using high-exposure (dose) animal studies to identify either man-made or natural chemicals as human carcinogens.

In recent years increasing attention has been given to developing safer products and technologies, especially when concerns have been raised with regard to the hazards of an existing product or technology. In some cases, the focus has been on developing products that do not have carcinogenic properties to replace products that have been classified as human carcinogens or probable or possible human carcinogens by IARC or as known or reasonably anticipated to be human carcinogens in the Report on Carcinogens prepared by the National Toxicology Program. Endpoints other than cancer have increasingly drawn attention for chemicals such as bisphenol A which has been under attack as an endocrine disrupting chemical. In general, chemicals that persist in the environment and have a long residence time in animals and humans, even when shown to have low hazard potential, have become targets for replacement. In yet other cases, the approach has been to identify replacements for chemicals that are persistent in the environment and have a long residence time in animals and humans. In other cases, the approach has been to find ways to minimize the use of the chemical viewed as being unsafe. These activities have given rise to a field of science sometimes referred to as “green chemistry” (Anastas and Warner, 1998).

Controversy has recently developed over cancer classification for new technologies or products with arguments developing over whether they are really safer. One example relates to diesel engine technology. Controversy continues over whether the particulate emissions from old diesel engines using high sulfur content fuels are or are not carcinogenic to humans (Hesterberg *et al.*, 2005, 2011). Much attention has been given to developing low emission, “green,” engines. The human epidemiological evidence for traditional diesel exhaust being carcinogenic based on epidemiological studies of occupational-exposed populations has been inconsistent. Long-term studies of rodents exposed to high concentrations of traditional diesel exhaust have been negative in Syrian hamsters and mice and positive in rats. The positive findings in rats have been attributed to an “overload phenomenon” and not been viewed as irrelevant to assessing human carcinogenic hazard.

Nonetheless, major effort has been given to improve reducing emissions by improving engine design, using ultra-low sulfur fuel, introducing exhaust after-treatment systems and using electronic control systems. Exhaust emissions from new technology diesel engines operating with ultra-low sulfur fuel (less than 15 ppm sulfur) of particulate matter and most other constituents are less than 1% of that observed for traditional diesel units (Hesterberg *et al.*, 2011). In my view, the emissions are so low they should be considered as “not carcinogenic to humans.”

Another new set of green products are reformulated synthetic glass fiber insulation products purposefully designed and produced to be “biosoluble” and lacking in carcinogenic properties (Hesterberg and Hart, 2001; Bernstein, 2007). The IARC (2002) previously determined that while it was appropriate to continue classifying some durable synthetic vitreous fibers as “possible human carcinogens,” it was not appropriate to classify “biosoluble” fibers with regard to human carcinogenic potential. The National Toxicology Program is currently evaluating how these new biosoluble glass fibers should be listed in the next Report on Carcinogens. Previous Reports on Carcinogens have treated synthetic vitreous fibers as a single category and classified the category as “reasonably anticipated to be human carcinogens.” An expert panel has unanimously recommended that the biosoluble glass fibers not be listed as “reasonably anticipated to be human carcinogens” while biodurable synthetic glass fibers continue to be listed as “reasonably anticipated to be human carcinogens.” It will be interesting to see how the NTP staff heeds this expert advice in formulating a final decision to list or not list biosoluble glass fibers as contrasted with durable synthetic fibers.

The outcome of the classification decisions for the new “green” technology (diesel engines with exhaust after-treatment devices and using ultra-low sulfur fuels) and green products (biosoluble glass fibers) have the potential for being precedent setting. If new “green” products/technologies cannot be accorded different cancer classifications than the products they replace, the public will be sent a confusing signal and industry may be reluctant to invest in developing new safer products. Conversely, recognition that the new products/technologies are safer may stimulate research and development on “green” replacement products and associated safety evaluation activities.

The situation in periodically re-evaluating the carcinogenic classification of a specific chemical is different than the re-evaluation of a technology or product. As noted for diesel engine technology and glass insulating fibers, they may change over time. Conversely, a specific chemical is always that chemical; however, the amount of information on the chemical will increase over time. Even with an increased body of knowledge, controversy

may continue. An example is formaldehyde which is both a normal constituent in the body as part of the 1-carbon metabolic scheme and also an important commodity chemical. A key issue in the controversy is the interpretation of weak epidemiological evidence of an association between inhalation exposure to formaldehyde and the occurrence of leukemia. Rhomberg *et al.* (2011) and Golden (2011) have critically reviewed the literature and emphasized the lack of biological plausibility for inhaled formaldehyde causing extra-pulmonary effects such as leukemia. A Committee of the National Research Council (NRC, 2011) has recently reviewed the Environmental Protection Agency's draft IRIS assessment of formaldehyde and addressed these issues.

Increasingly, the "precautionary principle" has dominated approaches to regulation of products and technologies. The concept took hold first within Europe and was codified by the European Commission (2002); more recently its use has been advocated in the United States. In its most simple form it argues that if the product or technology has not or cannot be viewed as safe then the product or technology should be replaced or not used. It is obvious that the "devil is in the details" with regard to the basis for characterizing what is safe or not safe. There is a continuum from safe products or technologies to highly hazardous products and technologies. Indeed, some highly hazardous products may be used in a controlled manner so they do not pose a significant health risk. Some advocates of the "precautionary principle" point to thousands of untested chemicals and argue they should be tested or banned. I would argue that a critical review of past experience with many of these chemicals or closely related chemicals provides a sound basis for their continued use. Quite frankly, additional extensive testing using laboratory animals may not be warranted.

The "precautionary principle" is a core element of the Registration, Evaluation, Authorization, and Restriction of Chemicals (REACH) program established by the European Commission (2006). More details are available at REACH (2011). Thoughtful reviews of the REACH program have been written by deAvila and Sandberg (2006) and Williams *et al.* (2009).

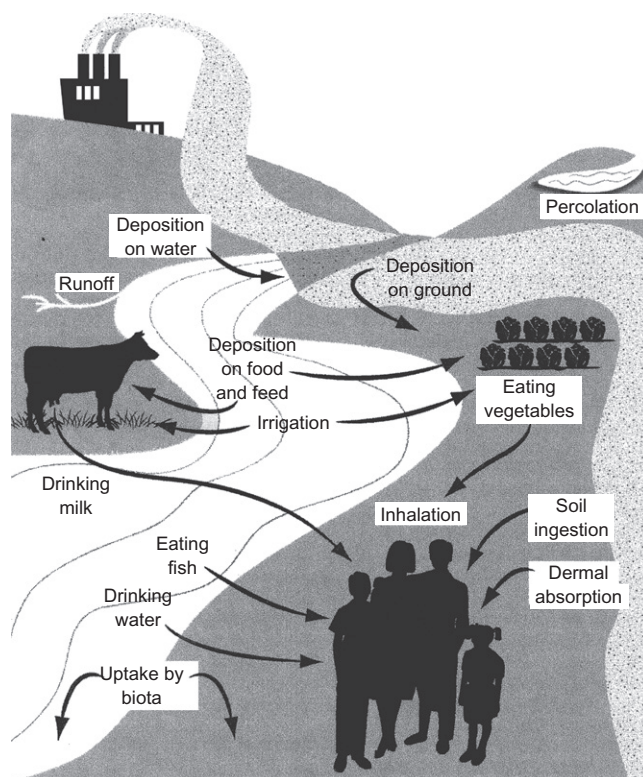

## A FRAMEWORK FOR ACQUIRING INFORMATION

### Linkages from sources to health impacts

The purpose of this section is to provide a conceptual framework for using information to evaluate specific cases of actual or alleged toxicosis and to facilitate the acquisition of new knowledge that will have impact in understanding potential toxic effects. Earlier, in Figure 2.1, a conceptual

framework was provided for evaluating the linkages extending from a source of a toxic material to manifestation of an adverse health outcome in an individual or a population. The conceptual framework is equally applicable to humans or other animal species.

The source to exposure linkage has been expanded in Figure 2.4 (Paustenbach, 2001). In this example, an industrial plant is illustrated as the source. The figure serves to illustrate the complex nature of the exposure pathways that may be encountered including the role of livestock. The focus in the figure is on the multiple pathways by which a potential toxicant may reach a human population; inhalation, drinking water, dermal absorption, ingestion of soil, and ingestion of a variety of food-stuffs including milk and meat from domestic animals. All of these pathways might also serve to expose the cow in the figure to the toxicant. Obviously, the quantities of the toxicant taken in by the single cow could also cause toxicity in a herd of cows. Equally as important is the role of the cow as a pathway for the toxicant to reach people. For example, the figure illustrates that a toxicant could be present in cow's milk and the milk could be consumed by people. The cow could also be slaughtered and the meat ultimately consumed by people. Thus, it is

**FIGURE 2.4** Schematic rendering illustrating exposure pathways extending from a source of toxicants to exposure of livestock and people (from Paustenbach, 2001).

important to recognize that the cow, or any other food animal species, can both manifest toxic effects and serve as a pathway for toxicants to reach people via the food supply.

It is readily apparent that the schematic rendering shown in Figure 2.4 can be expanded or contracted. In natural ecosystems, multiple species might be involved as a toxicant moves from a source or multiple sources via various pathways. In some cases, various species in the ecosystem may be impacted as individuals. Moreover, natural populations may be impacted. In addition, these pathways may ultimately result in the toxicant reaching people. An example is mercury in fish. In practice, veterinarians may encounter situations where poisonous plants in the pasture or in harvested forage may be the source of the toxicant. Feed may be contaminated at a mill and serve as the pathway by which a toxicant reaches the livestock. In other cases, the potential human toxicant may be a pharmaceutical purposefully given to the cow.

The utility of using the conceptual approach in Figure 2.4 can be illustrated using the transfer of a specific radionuclide,  $I^{131}$ , from the diet of cows to the cow's

milk to intake by humans and thyroid uptake. This situation was of concern when nuclear weapons were being conducted in the atmosphere resulting in worldwide fallout and for releases from reactor accidents in England (Windscale), Ukraine (Chernobyl) and Japan (Fukushima). Figure 2.5 illustrates the results of a controlled study conducted at the Hanford Laboratories, Richland, WA, in the early 1960s with  $I^{131}$  administered to dairy cows (Bustad *et al.*, 1965). The "old" radiation units of microcuries for quantifying the amount of radioactive material are used in the scale on the left and the "new" International System units of becquerels are used in the scale on the right. Rather than contaminate a large quantity of feed, the cows were given two feed pellets each day, the feed pellets all contained  $5\mu\text{Ci/l}$  (185 Bq) of  $I^{131}$  on the first day of the study. The  $I^{131}$  decayed with a physical half-life of 8.06 days so the cows ingested less  $I^{131}$  each day (the straight line in the figure). The cows' thyroids and milk were monitored for  $I^{131}$  content. Aliquots of the  $I^{131}$  contaminated milk were ingested by five volunteers and their thyroids were monitored for  $I^{131}$ . As an aside, the calculated radiation dose to the thyroids of the volunteers was less than what

Reprinted with modification from Bustad, McClellan and Garner, "The Significance of Radionuclide Contamination in Ruminants", pp 131-146, in *Physiology of Digestion in the Ruminants*, 1965, Butterworth, Inc.

**FIGURE 2.5** Inter-relationships for radioiodine ( $I^{131}$ ): intake by cows, cow's thyroid and milk and human thyroid (adapted from Bustad *et al.*, 1965).

would have been received from an  $I^{131}$  thyroid uptake study conducted for diagnostic purposes. Let me hasten to note that the control limits for radionuclides in milk intended for human consumption would be sufficiently stringent that the radiation dose to the cows would be much lower than required to produce toxicity in the cows. These results have been used to estimate allowable intakes from  $I^{131}$  contaminated milk and to develop guidance for monitoring pasture and hay to control milk contamination. Data such as presented in Figure 2.5 were useful input to the control of radiation exposure of Japanese populations from ingestion of milk following the Fukushima, Japan, accident in 2011, as they were earlier for European populations following the Chernobyl accident.

## Toxicokinetics

The simple schematic rendering shown in Figure 2.1 can be used to illustrate several important concepts. First, it is important to recognize that contrary to common usage, exposure and dose are not the same. The exposure environment is characterized by the concentration of the toxicant in the media, be it water, air or feed, the quantities taken in and the time course of the intake. Dose is the concentration, over time, of the toxicant in the various tissues of the subject, whether it be a cow, a human or a laboratory rat.

For example, in Figure 2.5 the exposure of the cows would be the quantity of  $I^{131}$  ingested. An example of dose would be the measured quantity of  $I^{131}$  in the thyroid of the cows and human volunteers. A more precise estimate of dose would be the calculated radiation dose in rem (old radiation unit) or sievert (new radiation unit).

The information presented in Figure 2.5 may be viewed as being a limited toxicokinetic study. The key data acquired were the intake of  $I^{131}$  and the changing concentration of  $I^{131}$  in the cow's thyroid and milk. The information on the relationship between  $I^{131}$  intake and milk content are sufficient to provide input for estimating limits of daily intake of  $I^{131}$  in forage by the cows in order to limit the  $I^{131}$  content of milk to some prescribed limit such as an Intervention Level as will be discussed later. Because the physical half-life of  $I^{131}$  is quite short, 8.06 days, and the  $I^{131}$  is concentrated in the thyroid and milk, concern does not develop for the  $I^{131}$  content of the rest of the carcass. If the radionuclide or specific chemical were found in edible portions of the carcass, then information on the radionuclide, chemical or metabolite of the chemical in the edible tissues such as muscle would be of interest. For example, radio-caesium (caesium behaves like potassium) concentrates in muscle and is also present in milk. Radio-strontium (strontium behaves like calcium) concentrates in the skeleton and milk.

The characterization of the kinetics linking exposure with dose is referred to as toxicokinetics (for a toxic agent) or pharmacokinetics (for a pharmaceutical). In actual practice, the term pharmacokinetics is frequently used when it would be more appropriate to use the term toxicokinetics. Several chapters in this book deal specifically with kinetics of toxicants and pharmaceuticals.

Toxicokinetics (see Figure 2.1) are used to describe the movement and disposition of the toxicant in the organism. This includes consideration of the route of entry; ingestion, inhalation, dermal or purposeful administration by injection. A complete description of the toxicokinetics of a toxicant will take into account: (1) the intensity and duration of the exposure, (2) the rate and amount of absorption of the toxicant from the site of entry, (3) the distribution of the toxicant within the body, (4) potential biotransformation to less, equal or more toxic form, and (5) the rate of excretion by route (urine, feces or exhalation). All of these aspects of toxicokinetics may be influenced by species differences in physiological and biochemical characteristics. Modern approaches to modeling toxicokinetics attempt to take account of both species differences and similarities in influencing the fate in the body of toxicants. It is also important to recognize that the exposure or dose level may influence the kinetics of a toxicant and its metabolite(s). This is an especially important consideration in extrapolating from laboratory studies that may be conducted at high doses to lower more environmentally relevant exposures/doses.

## Toxicodynamics

The linkage between dose and adverse health outcome shown in Figure 2.1 involves multiple mechanisms as various toxicants may potentially impact all the cells and organ systems of the body. Increasingly, scientists have attempted to model these relationships which, in parallel to the nomenclature for the kinetic phase, are called toxicodynamic or pharmacodynamic models. It is obvious that multiple pathways may be involved in a toxicant producing disease and that knowledge of the individual steps will increase as knowledge of basic biological mechanisms increases. For example, the explosion of knowledge of basic biology at the level of the genome (genomics), proteins (proteomics) and metabolism (metabolomics) has provided a basis for exploring the mechanistic basis of toxicant-induced disease with a degree of refinement that could not even be envisioned even a short time ago.

A later chapter reviews the basic mechanisms of toxicity. In addition, many of the chapters on organ toxicity and specific toxicants contain detailed information on mechanisms of toxicity. As the reader reviews this material, and especially the detailed discussion of

biochemical mechanisms of action, it will be important to place those in the context of processes at the cellular and tissue level; i.e., inflammation, cell death, cell proliferation, hypertrophy, hyperplasia, metaplasia and neoplasia. A strength of the veterinary medical curriculum, as with the human medical curriculum, is the emphasis given to understanding both normal body processes and disease processes extending from the molecular level to cells to tissues to organs and, ultimately, to the integrated mammalian organism. A special opportunity exists for medically trained personnel, both veterinarians and physicians, to put the expanding knowledge of molecular and cellular processes into the context of overt disease. After years of emphasis on a reductionist approach to basic biomedical science, it has become recognized that this approach needs to be complemented by an integrative approach. This has recently been termed systems biology. In my view, this is not really a new concept. It is more a rediscovery and refinement of the concepts of integrated biology and pathobiology used in veterinary medicine for decades.

There has been great enthusiasm for the use of mechanistic information in safety/risk evaluations as will be discussed later. Recognition of the difficulty of characterizing all of the individual mechanistic steps has given rise to a new term – mode of action. The mode of action has been defined as the dominant step(s) involved in producing a given toxic endpoint. An example is the role of cell killing as the mode of action for large intakes of chloroform (Butterworth *et al.*, 1995) or formaldehyde (Conolly *et al.*, 2004), over extended periods of time causing tumors in rodents. The exposure–response relationship for cell killing may likely have a threshold which must be considered in extrapolating the findings from high exposure-level studies in rodents to humans exposed to low concentrations of these chemicals. Readers interested in a contemporary view of the use of mode of action information to improve regulatory decision making will be interested in a summary paper by Carmichael *et al.* (2011).

It is my contention that understanding the basic concepts conveyed in Figures 2.1, 2.2 and 2.4 can be very useful in investigating a range of situations where the objective is to establish or refute a causal association between a given source and toxic agent and an increased incidence of an adverse health outcome. The term increased incidence is used advisably, recognizing in most situations involving domestic animals, either as commercial herds or as companion animals, that the situation is one of presence or absence of a given disease and the “ruling out” of other differential diagnoses. However, in situations involving human populations the issue frequently encountered is whether a given toxicant exposure has caused an increase in a disease, recognizing that most diseases may have multiple etiologies, for example

hypertension and diabetes. This is especially the case in evaluating diseases that typically occur late in life, such as cancer and chronic diseases, and with exposure to toxicants that may occur at low levels over long periods of time. In some cases, such as lung cancer and cardiorespiratory disease in humans, a risk factor such as cigarette smoking is so substantial it is a challenge to determine if low-level exposure to other toxicants such as air pollutants is having chronic effects at low exposure concentrations.

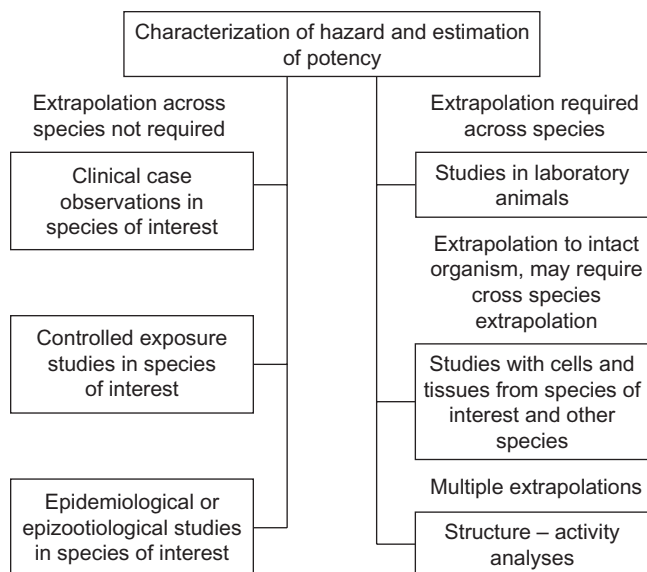

### Veterinary toxicology is multi-faceted

It will be apparent to the reader of this book that veterinary toxicology is multi-faceted. Thus, there are many ways to organize and synthesize the knowledge base that we call veterinary toxicology. One dimension is the various classes of toxicants. Another dimension of the field relates to the media that contains the toxicant; air, water, soil and feed. Another dimension considers the various routes of exposure of toxicants; inhalation, ingestion, dermal or purposeful injection. It is also convenient to consider the various organ systems and processes that may be affected by toxicants. This is the basis for organization of a major section in this book. It is also important to consider the individual toxicants or classes of toxicants. This approach is used in organizing another major section of this book. Finally, veterinary toxicologists recognize the necessity of considering the various species of concern. Increasing veterinary medical practitioners have become more specialized with many focusing their clinical skills on a single species. This book does not include a section addressing the toxicology of individual species. To have done so would have substantially increased the size of this text. However, chapter authors have endeavored to discuss species variations in responses to toxic agents. It is noteworthy that several textbooks, those of Petersen and Talcott (2006) and Poppenga and Gwaltney-Brant (2011), focus on small animals. Some of the major comprehensive veterinary medicine texts, such as the *Current Veterinary Therapy* series, which focus on other species include chapters on toxicology related to that species.

## SOURCES OF INFORMATION

### Case observations in the species of interest

There are multiple sources of scientific information for characterizing the relationship between exposure to a toxicant and toxicant-induced response. Figure 2.6 is a schematic rendering of the multiple sources of information that may be used to understand the toxicity of a given agent.

**FIGURE 2.6** Sources of information for evaluating potential toxicants.

As discussed earlier, the origins of veterinary toxicology and toxicology in general, are both rooted in observations. An adverse health effect, either a pattern of morbidity or death in an individual or population, is observed and the disease linked to exposure to a toxicant. Typically, the time interval between exposure and the adverse health outcome was brief which aided in deducing an association. Because the causal association was identified in the species of interest, whether it be a person, a horse or a cow, it was not necessary to extrapolate between species. Nor was it necessary to explore in-depth the mechanistic basis for the causal association to either diagnose a particular case or prevent future cases. Action to prevent exposures and, thus, prevent disease could be based on empirical observations.

As you read many of the chapters in this book, you will note that details of the mechanism by which a particular toxicant causes disease have been elucidated to a variable extent. When the toxicant is exclusively of concern in veterinary medicine and has no implications for human health, there has been limited impetus for developing a mechanistic understanding of how a toxicant causes disease. Concern for human health has been a major driver of the biomedical research agenda. An obvious exception is when the toxicoses observed in veterinary medicine have large economic impact or toxicants can reach people via animal products.

There are many circumstances where observational knowledge is not adequate and it is necessary to conduct experiments to characterize the toxicology of an agent. It is obvious that if concern for the potential toxic response is in a non-human species, controlled experiments

can be conducted using the species of interest. This is obviously the case for domestic livestock as well as companion animals.

A much more common situation is when concern focuses on potential toxicity of a newly developed agent for use in people or animals. For example, it is necessary to establish the safety of a potential new pharmaceutical or consumer product before it is introduced into commerce. In these instances experimental animals are used as a “first approximation” of the safety of the new compounds to humans. In the case of products intended for use in animals, studies on both efficacy and safety can be conducted in the species of interest. This remains an imperative step in the safety evaluation of new products. There are also circumstances in which it is desirable to extend limited observations from opportunistic studies on people or animals that have been exposed. When a new product is developed and marketed, either a pharmaceutical or a consumer product, various post-marketing surveillance systems should be put in place to attempt to detect any unexpected adverse outcomes.

### Epidemiological/epizootiological studies

If a particular chemical has been used for an extended period of time and human exposure has occurred either in the workplace or from the environment, it may be feasible to conduct epidemiological studies. Epidemiology is the study of how disease is distributed in the population and the factors that influence or determine this distribution. The design of a particular epidemiological study will be guided by the hypothesis being tested and the nature of the population(s) available for study. As an aside, the term epidemiology (epi for across, dem for people and ology for scientific study) is applicable to people while the more appropriate related term for studies on animals would be epizootiology (epi for across, zoo for animal and ology for scientific study). The details of conducting epidemiological or epizootiological studies are beyond the scope of this chapter. A relevant reference for basic concepts in epidemiology is the text by [Gordis \(2008\)](#).

A classic paper by [Austin Bradford Hill \(1965\)](#), a British medical statistician, provides guidance on the interpretation of epidemiological evidence for a given agent or factor causing a health effect ([Table 2.1](#)). Although developed for interpreting epidemiological data, i.e., data acquired on human population, the guidance is also highly relevant to interpreting data acquired on animal populations. The framework needs to be used intelligently rather than slavishly – it is a guide and not a checklist.

Retrospective epidemiological studies may be feasible for previously introduced agents for which prior exposure has occurred or prospectively for a newly introduced agent. If the agent is new it is obvious that it is not feasible

**TABLE 2.1** Bradford Hill (1965) guidance for interpreting epidemiological evidence for a given agent or factor causing a specific disease

*Strength:* If there is a large effect size (a strong effect), this makes a true causal relationship more likely. There is no fundamental reason why a strong association should be more likely to be causal than a weak association. However, Bradford Hill was thinking of possible confounding factors and argued that if a strong association is not causal, an association with some other factor that varies closely with the factor originally suggested must exist. If the association is strong, this co-variable will be easier to recognize than if the association is weak.

*Consistency:* Is there evidence for the same findings from more than one study, preferably from different settings?

*Specificity:* Is the effect specific to the exposure? In reality this rarely occurs, and some regard this as the “icing on the cake” when considering causal evidence. However, the specificity of a particular mechanism, if seen across a range of health endpoints, would meet the requirements of this component.

*Temporality:* This is the only absolute. Exposure must precede outcome.

*Biological gradient:* Is there a dose–response relationship? In addition (although explicit in Bradford Hill’s original paper), is there a threshold of exposure below which an effect is not seen?

*Plausibility:* Does this exposure–effect relationship make biological sense? Is there mechanistic evidence to support the likelihood that this might occur given current knowledge? Bradford Hill pointed out that this feature should not be demanded: what is implausible today may be entirely plausible tomorrow.

*Coherence:* Does the proposed causal association cohere with other findings? For instance, if we were concerned that a specific exposure might be related to a health effect that was based on an inflammatory response, has a similar effect been seen with other inflammatory conditions, or is an apparent effect on mortality accompanied by effects on morbidity?

*Experiment:* Is there evidence from experiments (involving either animals or humans, whether individually or as populations) that removal of the exposure reduces the effect?

*Analogy:* Are there analogous situations that would tend to support the likelihood of a causal relationship? For instance, when considering a possible teratogen, consideration of the effects of thalidomide on the developing fetus would come to mind.

to conduct epidemiological studies to retrospectively evaluate the potential safety/hazard of the agent. If the ultimate interest is in the effects on people, it may be feasible to conduct controlled exposure studies with human volunteers. It is advisable for the planning of such studies to be based on a solid database on the potential toxicity of the agent acquired from studies in laboratory animals. The design and conduct of such human studies must be guided first and foremost by ethical considerations (NRC, 2004). If a non-human species is the target species of concern, then it is obvious that the most relevant information is that acquired from studies conducted in that species.

## Experimentation

An additional option for acquiring information is to conduct toxicological studies in typical laboratory animal species. Such studies are the cornerstone of research conducted to evaluate the safety/risk of newly synthesized agents whether they be a potential new pharmaceutical, pesticide or herbicide, a significant consumer product or a new chemical or intermediate to be used in commerce. It is well recognized, certainly by veterinarians, that no single laboratory animal species is a miniature version of the human species, i.e., 15 cm in height, weighing 180 grams and sharing all of the common biological traits and diseases of humans. Fortunately, humans and laboratory animals do share many common biological traits and diseases. Knowledge of the extent to which there are similarities and differences between humans and a given

laboratory animal species can be used to guide the selection of a species to serve as a surrogate for humans in developing data for safety/risk evaluations for humans. It is encouraging that some veterinary medical schools are recognizing the importance of extending the range of species studied in the core curriculum from the usual companion animal and domestic livestock species to include the common laboratory animal species.

At this juncture, it is appropriate to note the importance of animal welfare issues. The Animal Welfare Act (AWA), initially enacted in 1966 and amended in 1970, 1976, 1985, 1990 and 2002, is the principal federal statute in the U.S. governing the sale, handling, transport and use of animals. The AWA applies to all species of warm-blooded vertebrate animals used for research, testing or teaching excluding animals used for agricultural research. The U.S. Department of Agriculture, Animal and Plant Health Inspection Service (APHIS) has responsibility for implementing the AWA. The 1985 Amendments to the AWA clarified the importance of humane care, minimization of pain and distress, consideration of alternatives, the role of institutional animal care and use committees, the psychological well-being of primates and exercise for dogs. The primary reference on animal care and use is the *Guide for the Care and Use of Laboratory Animals* prepared under the auspices of the Institute of Laboratory Animal Resources of the National Academy of Sciences/National Research Council (ILAR, 2010). All toxicologists involved with laboratory investigations should be familiar with the contents of the Guide irrespective of the species they use for their research.

An additional matter the experimentalist should be aware of is the need for use of good laboratory practices (GLPs) in the conduct of research intended to be used for regulatory decisions. Both the FDA (FDA, 2001) and the EPA (TSCA, 1985; FIFRA, 1991) have requirements for the use of GLPs. The FDA GLP requirements do not extend to exploratory, mechanism of action or efficacy studies. The basic elements of GLPs are: (1) the appointment by the institution of a study director, (2) the use of an independent quality assurance unit, (3) the use of documented standard operating procedures, (4) a written protocol for each study, and (5) preparation of a final report containing a GLP compliance statement for each study. The use of GLPs is not required by FDA for studies with domestic livestock. However, investigators conducting studies using domestic livestock would be well advised to attempt to adhere to the basic principles that undergird GLPs to help ensure the quality and reproducibility of the data being generated.

Another option for acquiring useful toxicity data is to conduct investigations *in vitro* using tissues or cells from mammalian species, both humans and laboratory animals, and using bacteria and yeasts. An additional option is to conduct structure–activity analyses on the new agent using the large data bank of structure–activity information already available on other related chemicals.

All of the options outlined, to some extent, create extrapolation issues. Even if studies are conducted in the species of interest, it is typically necessary to extrapolate from the high levels of exposure or administered doses studied experimentally to lower exposures or doses anticipated to be representative of intended use. It may also be necessary to extrapolate from a relatively short period of study, say days or a few weeks, to the intended period of use, over months or years. If the studies are not conducted in the species of ultimate interest, there is need to extrapolate between species. It may also be necessary to extrapolate observations made in a population of healthy individuals to a population that includes individuals with pre-existing disease or altered susceptibility to development of disease. Some aspects of the extrapolation between species and across exposure/dose levels may be facilitated by physiologically based toxicokinetic and toxicodynamic modeling. However, toxicodynamic modeling is still in its relative infancy.

It is important to recognize that even with today's level of knowledge of these extrapolation issues, it is not possible to estimate, with absolute certainty, the precise numerical level of human exposure to a given agent that may be without any risk of potential harm or will produce a specific level of harm. This is generally recognized in contemporary safety/risk evaluation methodology such that conservative approaches are used in estimating safe levels of human intake of chemicals. By taking a conservative approach to setting standards or providing

guidance to limit exposures, there can be a high degree of confidence that an agent can be used safely if used as intended. Ultimately, all processes that develop guidance or standards to limit exposures and thus limit disease require judgments to be exercised. In short, science can inform the standard or guidance development process; however, it cannot prescribe specific standards.

## Schematic experimental designs

The experimental design for testing of any specific hypothesis must be matched to the hypothesis, the desired statistical power and the resources available. Inevitably, decisions on an experimental design involve making difficult choices among options because of resource constraints. In this section, two schematic experimental designs will be discussed to illustrate some of the key issues that must be addressed in planning toxicological studies. The discussion in both cases will assume that the species to be used in the study has already been selected.

## Acquiring toxicokinetic data

The first conceptual design, Figure 2.7, illustrates an approach to acquiring data for understanding the link between exposure and internal dose, the kind of data that can be used for toxicokinetic modeling. Recall the toxicokinetic linkage in Figure 2.1. The design shown is based on a single brief intake of the test agent. However, the design can be modified for studying chronic intake of an agent. A critical decision is the choice of the route of administration or intake of the test material. Obviously, such studies are most readily carried out with parental administration of the agent. This may be the most appropriate route for a pharmaceutical agent that is to be parentally administered. However, the resulting data may be of limited relevance to other routes of intake. For example, it may not appropriately mimic oral

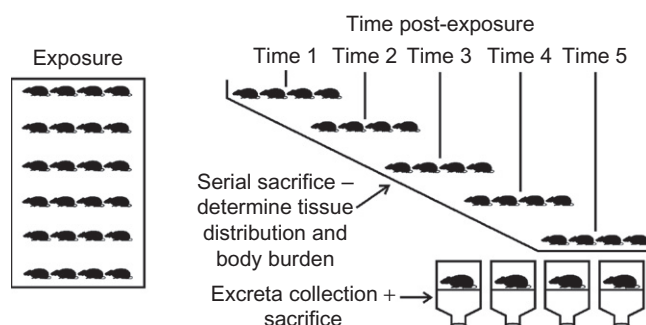

FIGURE 2.7 Schematic rendering of an experimental design for evaluating the kinetics of an administered toxicant.

intake since only a small fraction of some toxicants may be absorbed from the gastrointestinal tract. In short, the route of administration should be matched to the route of concern for real-world exposure to the agent.

With inhalation, the particle size distribution of the airborne toxicant will influence what portion of the inhaled material will be deposited and where it is deposited in the various regions of the respiratory tract. The pattern of retention and subsequent translocation of the deposited material will depend on the size, chemical composition and dissolution properties of the deposited material. Individuals interested in details on the conduct of inhalation toxicity studies will find the book edited by McClellan and Henderson (1995) of interest as well as a summary chapter by McClellan *et al.* (2006).

Another key decision is whether conduct of the toxicokinetic studies may be facilitated by using a test agent labeled with radioactive or stable element tracers. Analytical considerations for the initial toxicant as well as any metabolite are of major importance in the conduct of toxicokinetic studies.

The schematic design (Figure 2.7) shows a group of animals maintained for collection of excreta and, perhaps, even sampling of expired air. Data from these analyses can be used along with tissue analyses to obtain a mass balance between the quantity administered and the quantity recovered. The schematic design shows multiple times at which animals will be euthanized and tissues collected for analysis. This allows the development of a dynamic profile of how the body handles the administered material. For organic compounds, provision needs to be made for analyzing both the parent compound and potential metabolites.

The selection of the sacrifice times will be guided by the anticipated kinetic profile of the agent and its metabolites. It may be useful to obtain preliminary information on retention kinetics from pilot studies. Some organic compounds may be rapidly metabolized leading to the need to schedule all of the sacrifices over a few hours. On the other hand, certain inhaled relatively inherent materials may have long-term retention in the lungs extending over hundreds of days. It is important to recognize that the quantity of material administered may influence the kinetics of the material. Hence, it is desirable to use multiple administered exposure/dose levels as an experimental variable. Without question, the design of any particular toxicokinetic study requires the exercise of considerable professional judgment. Toxicological research is not a “cookie cutter” or “check the box” science.

### Acquiring exposure (dose)–response data

A schematic experimental design for a study to evaluate exposure (dose)–response relationships for toxicants

is shown in Figure 2.8. Recall the exposure–response linkage shown in Figure 2.1. The design shown is typical of that which might be used in the conduct of a 2-year bioassay, typically to evaluate carcinogenicity in rats and mice. The same design, and indeed the same experiment, can be used to evaluate other endpoints and to conduct shorter-term studies. The study should involve administration of the material by a route matched to likely exposure conditions to be encountered with the agent. Administration of an agent by gavage may be acceptable as a surrogate for ingestion, especially when it is desirable to administer specific quantities of material. However, I am not enthusiastic about the repeated use of gavage as a substitute for ingestion of an agent in feed. The use of intratracheal instillation as a surrogate for conducting inhalation exposures to an agent remains controversial. It is my professional opinion that intratracheal administration is a non-physiological mode for delivery of materials to the respiratory tract. It may result in exaggerated quantities of material being deposited in some regions of the respiratory tract while other regions are spared any exposure. This unusual pattern of distribution of the agent is very likely to influence the toxic responses of the airways and alveoli. Thus, I am hesitant to even recommend intratracheal instillation for mechanistic studies; the mechanistic information acquired may be irrelevant to the inhalation exposure situations that are of concern for people or other species.

It is critical that exposure–response studies utilize multiple exposure levels, perhaps three or four exposure levels. The choice of the specific exposure levels is one of the most important decisions to be made in planning such studies. One consideration relates to the potential level(s) of exposure to be encountered with intended use. Higher additional levels can be selected above this base level. Selection of exposure/dose levels can also be informed by the results of the kinetic studies. For example, it would not be desirable to use only exposure levels above a level at which metabolic processes are saturated. Another

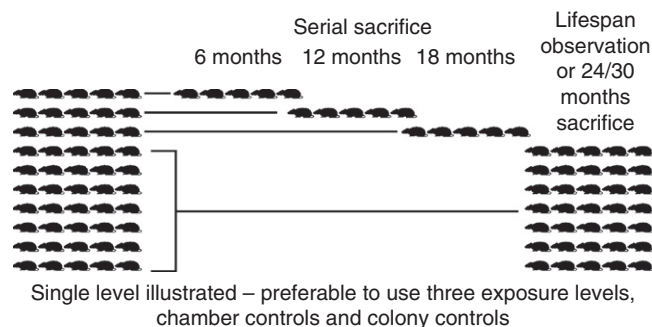

FIGURE 2.8 Schematic rendering of an experimental design for evaluating exposure (dose)–response relationships for a toxicant.

consideration emphasized by the EPA and NTP, especially when cancer is an endpoint, is to select a maximum tolerated dose (MTD) level as the highest exposure/dose level and establish lower levels by some fraction of the MTD level, perhaps 1/2 and 1/4 or 1/3 and 1/9. The use of an MTD has been justified on the grounds that it is necessary to maximize exposure to potentially observe carcinogenic responses recognizing the blunt experimental approach (NRC, 1993). A useful review on the history of the use of animal bioassays to predict carcinogenicity has been authored by *Beyer et al.* (2011).

The extent to which animal bioassays are a blunt approach to detecting the carcinogenic potential of agents is illustrated in *Figure 2.9*. It can be noted that for a species and strains of animals with a background incidence of 1%, a study of 50 animals will require a 20% response to detect a statistically significant effect. As an aside, a population of non-smoking people will experience about a 1% lifetime incidence of lung cancer. A population of a two pack a day cigarette smokers will experience about a 20% lifetime incidence of lung cancer compared to the 1% expected in non-smokers. Consideration of statistical information such as these emphasizes the importance of using care in interpreting the results of cancer bioassays using the typical 100 animals per exposure level. The interpretation of the relevance of the results of animal studies for estimating human hazards will be greatly enhanced by knowledge of the mechanisms involved in the toxicant causing disease in the animals.

A key feature of the exposure–response experimental design illustrated in *Figure 2.8* is the use of multiple sacrifice times for all exposure levels. In some cases it may be possible to evaluate the functional status of organs at these times, i.e., pulmonary function. In animals with inhalation exposure, when a respiratory tract response is of concern, it may be feasible to collect bronchoalveolar

lavage fluid samples for analysis of biochemical and cellular parameters. Most importantly, tissue samples can be collected for histopathological evaluation. The information obtained from the serially sacrificed animals, combined with that obtained from the terminal sacrifice animals, can provide valuable insight into the progression of disease processes over the course of the study. Without question, insight into the pathogenesis of toxicant-induced disease processes will be much more complete when serial sacrifices are conducted than that obtained only from an evaluation of the terminal sacrifice animals. Another option in the design of exposure–response studies is to include a group of animals at each level that are removed from further exposure at one or more times post-inhalation of exposure for maintenance without further exposure. These animals may be euthanized at later times and evaluated for evidence of recovery or reversibility of earlier toxicant-induced changes.

The basic guidance for using multiple exposure (dose) levels and making experimental observations at multiple times is as applicable to the conduct of studies examining hypotheses on the mechanisms of action of toxicants as it is to studies developing information for regulatory decisions. I remain disappointed at the number of published papers on mechanisms of action of specific toxicants that fail to use multiple exposure (dose) levels and multiple observation times. It is only when exposure (dose) level and duration of exposure are included as experimental variables that a true understanding of the mechanisms of toxicity for an agent can be elucidated. Mechanisms are frequently exposure (dose) level and exposure duration dependent.

As the science of toxicology has advanced, increasing attention has been given to developing specialized approaches for evaluating toxicity induced in different organ systems. The various guidelines developed by the USEPA, FDA and NTP are useful references for these specialized approaches. For example, the EPA has published guidelines for evaluating carcinogenicity (EPA, 1996a), gene mutation (EPA, 1996b), reproductive toxicity (EPA, 1996c), developmental toxicity (EPA, 1991) and neurotoxicity (EPA, 1995). The EPA is continually reviewing and updating its guidelines for toxicity testing. Forty-nine harmonized health effects test guidelines used in the testing of pesticides and toxic substances have been developed and can be found on the EPA Office of Prevention, Pesticides and Toxic Substances website (EPA/OPPTS, 2006).

The FDA has provided specific guidance for evaluating the safety of compounds used in food-producing animals (FDA, 1994) and principles for evaluating the safety of food ingredients (FDA, 2011). The EPA has provided guidelines for evaluating the safety of products intended for use with cats and dogs (EPA, 1998) and domestic livestock (EPA, 1996d).

**FIGURE 2.9** Relationships between number of subjects required to detect excess risk and the level of detectable excess risk.

A special issue of concern with pharmaceutical products is the presence of trace contaminants and whether these trace contaminants should be tested individually. One approach to addressing this issue is the use of a “threshold of toxicological concern” concept championed by Kroes *et al.* (2005). Kroes, now deceased, was a Dutch veterinarian who developed an excellent reputation in safety and risk assessment. The concept of “safety qualification thresholds” (Ball *et al.*, 2007, 2011) developed out of the “threshold of toxicological concern” concept. It is a promising approach to minimizing the use of laboratory animals in exhaustive testing while still assuring the safety of pharmaceuticals. The European Medicines Evaluation Agency (EMA, 2004) has provided detailed guidelines for addressing genotoxic impurities.

The various guidelines are useful for planning safety evaluation studies. However, the guidelines should not be used as a substitute for the use of professional judgment in planning, conducting and interpreting toxicological investigations. As noted earlier, toxicology is not a “cookie cutter” or “check the box” science.

## TOXICOLOGIC DESCRIPTORS

### Toxicology rooted in observations

The results of toxicological investigations, either from clinical case observations or planned experimentation, involve describing the exposure, the dose, the response and inter-relationships between these parameters. Exquisite knowledge of exposure or dose or response is not sufficient. Ultimately, it is necessary to understand their inter-relationships. With clinical case observations, the initial emphasis is on the clinical findings – what are the response and the need, on the basis of a differential diagnosis, to establish that a toxicant is or is not involved. The evidence for a specific toxicant may be based initially on clinical findings complemented by gross necropsy findings potentially buttressed by histopathological findings. The differential diagnosis of a toxicosis may be strengthened by evidence of a marker of dose, i.e., urine, blood or tissue levels of suspected toxicant. The diagnosis may be further strengthened with evidence of exposure, i.e., the presence of the toxicant in the feed or identification of a poisonous plant. At each step, the qualitative evidence of a toxicosis and a specific toxicant is enhanced as qualitative findings are supplemented by quantitative findings. The analysis is not completed there, though. Other reasonable differential causes of the same or similar clinical signs must also be “ruled out” if the animals or humans are in a real world or field setting.

### Quantifying exposure

Quantitation is paramount in evaluating exposure. In the experimental setting, quantitation is considered beginning with the design of the study and continuing through all aspects of the experimentation. To the extent feasible, exposure to the toxicant should be rigorously characterized. This starts with physical and chemical characterization of the test material, be it an alleged pure compound or a mixture, including identification of any contaminants. The exposure circumstances need to be rigorously characterized. This, of course, is easiest to do when the test material is administered by injection. Even with injection, care must be taken to ascertain that the desired quantity of toxicant was actually injected. The quantity administered is typically related to the body weight of the subjects.

With administration by routes other than injection, the situation becomes more complicated. This may involve providing the experimental subjects’ feed to which the toxicant has been added. If this approach is used, samples of the contaminated feed should be collected periodically for analysis of the test agent. In some cases, the concentration of the test agent in the feed will be used as a measure of the exposure. To accurately quantify exposure, it will be necessary to know the concentration of the test agent in the feed and also determine the quantity of the contaminated feed containing the test agent that has been ingested. For dermal administration, it is necessary to know the concentration of the test agent in the liquid media applied to the skin and the quantity of the media applied to the skin.

The situation is much more complex for a test agent in the air, whether it is a diluted gas or suspended particulate material. In both cases, it will be necessary to sample and measure the concentration of the test agent in the air at a location as close to the breathing zone of the experimental subjects as possible. For both particulate material and reactive gases, there may be substantial loss of the test agent in the delivery system between the generator used to create the test atmosphere and the breathing zone of the subject(s). Care needs to be taken to minimize such losses. For a toxic agent in a particulate matter form, it is essential to know not only the concentration of the test agent, but the size distribution of the particulate matter since the aerodynamic particle size distribution will influence the fraction of the inhaled material that will be deposited and where it deposits in the respiratory tract. In some experiments, it may be possible to use a plethysmograph to measure respiration of individual subjects during inhalation exposure. This is most readily accomplished when the exposure period is relatively brief as in a study of the toxicokinetics of the agent. The total quantity of test agent inhaled can be estimated from knowledge of the air volume inspired and the concentration of

the test agent in the air. In many studies the air concentration of the test agent may be used as a surrogate measure of exposure. As indicated earlier, exposure and dose are not synonymous. However, in many studies it may be necessary to use the concentration of the test agent in the feed, water or air as a surrogate measure of dose.

## Describing absorption, distribution, metabolism and excretion

A number of different parameters may be evaluated in assessing the kinetics of a test agent (recall Figure 2.7). Some of the common parameters and terms used are shown in Table 2.2 adapted from Spoo (2004). The four key events involved are absorption, distribution, metabolism and excretion. It is important to recognize that species differences may exist for each of these events. Absorption is the amount of the material that enters the body. As already discussed, the concept is simple. However, in reality it becomes complex as one moves from parental administration to oral intake, to dermal uptake, or inhalation exposure. Distribution of the material will be influenced by the route of entry and the physicochemical properties of the test agent. Metabolism for compounds varies dependent on the physicochemical properties of the material. In some cases, the material

may be very inert and simply be transferred mechanically within the body with some portion excreted over time. In other cases, especially with organic compounds, the metabolism may be quite complex and result in metabolites that are either more toxic, less toxic or have toxicity similar to the parent compound.

Excretion or elimination of the material and its metabolites, if metabolized, may occur via the kidney (urine), gastrointestinal tract (feces), or the lungs (exhalation of volatile compounds). In addition, the agent or metabolites may appear in tears, sweat or exfoliated skin. Some species, such as the rat, may engage in coprophagy, ingestion of feces, such that the test material in the feces is ingested and some portion passes through the body multiple times. Animals may be euthanized at various times during the course of the study and samples of various tissues collected and analyzed for the test agent or metabolites. With small experimental subjects, it may be possible to analyze all the tissues and obtain an estimate of the total body burden of the test agent and metabolites.

In some short-term studies it may be possible to collect and analyze excreta and expired air, if the compound is metabolized to a form that will be present in expired air. This information, along with the results of tissue analyses, can provide an estimate of the total quantity in the body, excreta and expired air for comparison with an estimate of the quantity administered. This kind of mass

TABLE 2.2 Common terms used to describe the ADME characteristics of chemicals (adapted from Spoo, 2004)

Term	Abbreviation	Definition
Concentration	$C_p$	Concentration of a chemical in plasma (p) at a specific time (t)
Time	$t$	Chronological measurement of a biological function
Half-life	$t_{1/2}$	Time required for exactly 50% of a drug to undergo some defined function (i.e. absorbed, distributed, metabolized or excreted)
Volume of distribution	$V_d$	Unitless proportionality constant that relates plasma concentration of a chemical to the total amount of that chemical in the body at any time after some pseudo equilibrium has been attained
Volume of distribution (steady state)	$V_{d(ss)}$	Same as $V$ , except measured when the chemical has reached a steady state in the body
Area under the curve	AUC	Total area under the plasma chemical concentration curve from $t = 0$ to $t = \infty$ after the animal receives one dose of the chemical
Body clearance of a chemical	$Cl_B$	The sum of all types of clearance from the body
Renal clearance of a chemical	$Cl_R$	Volume of chemical that is completely cleared by the kidneys per unit of time (ml/min/kg)
Non-renal clearance of a chemical	$Cl_{NR}$	Volume of chemical that is completely cleared by organs other than the kidneys per unit of time (ml/min/kg)
Dose	D	The amount of chemical that is administered to an animal; can be further defined as the total dose, that total dose the animal was exposed to, or the absorbed (effective) dose, that being the fraction of the total dose that was actually absorbed by the animal
Bioavailability	F	Also known as systemic availability of a chemical. The quantity of percentage portion of the total chemical that was absorbed and available to be processed (CME) by the animal, in the case of intravenous administration, $F = 100\%$

ADME: absorption, distribution, metabolism and excretion; CME: chemical metabolism and excretion.

balance approach is obviously most feasible when radioactive or stable isotope tracers are used. One should not be surprised to find the estimated quantity recovered varying from 75 to 125%; there will be a high degree of experimental variability when multiple samples are being collected and analyzed. Obviously, one should view with suspicion data tables showing recovery of exactly 100% of the administered dose. Such values are typically the result of an overzealous investigator normalizing the data to 100% recovery. For chronic exposure studies, it may be possible to use kinetic modeling to estimate the quantity of the test agent or metabolites present in the experimental subjects at each exposure concentration at various times after initiation of exposure.

### Toxicant-induced responses

The types of studies typically used by toxicologists to investigate exposure–response relationships can be placed in four categories related to the duration of the studies; acute, sub-acute, sub-chronic and chronic (recall Figure 2.8). Acute studies are usually of a day or less and may involve intraperitoneal, intravenous or subcutaneous injection, gavage, dermal application or inhalation. Injections may be given once or several times in the 24-hour period. Acute inhalation exposures are typically 4 to 6 hours in duration. In all cases, the observations are made over a 24-hour period. Sub-acute studies typically involve repeated exposures made on a daily, or 5 days per week, basis for 2 to 4 weeks with observations over the same period of time. Sub-chronic studies are usually conducted over a period of 1 to 3 months. In the case of inhalation exposures, these are typically conducted for 4 to 6 hours per day, 5 days per week. Chronic studies are usually conducted for more than 3 months and, most typically, for 2 years. I personally view the use of the terms acute, sub-acute, sub-chronic and chronic as jargon and prefer to communicate the duration of studies in a specific manner, i.e., number of days or months, or as short or long term. I prefer to use the terms acute, sub-acute, or chronic as descriptors of a medical condition.

The kinds of toxicant-induced responses that may be encountered are broad, essentially mirroring the range of disease processes that may occur in humans and other animal species. In any well-conducted toxicity study, the investigator should use as broad an array of observational techniques as are reasonably available to characterize the pattern of morbidity and mortality that may develop. Inevitably, cost constraints will influence the choice of endpoints evaluated. It will be useful to prioritize the potential endpoints as to their likely value in terms of the information gained. It is crucial that detailed necropsies be conducted on subjects euthanized at prescribed times and at termination of the study. Tissues

should be collected from any gross lesions and tissues identified in the protocol as likely target tissues and processed for histopathological evaluation. It is now routine to establish a defined set of criteria for evaluating the various tissues and characterizing lesions. This approach allows the quantitative evaluation of any pathological findings on a group basis rather than restricting the evaluation to qualitative descriptions of responses in individual subjects.

Toxicity studies to evaluate exposure (dose)–response relationships may extend from minutes to hours when biochemical and physiological responses are being evaluated, to hours to days when acute morbidity and mortality are being assessed, to weeks to months and finally to a significant portion of the lifespan of the species, for example 2 years for mice and rats when chronic effects, including cancer induction. With increased attention given to animal welfare considerations, emphasis is being given to using as few animals as possible to define the acute morbidity and mortality of test materials. Rather than use a traditional approach to attempt to precisely define a lethal dose 50% ( $LD_{50}$ ), it has become customary to use approaches with many fewer animals to define an approximate  $LD_{50}$ . In some cases, it may be desirable to determine the concentration of a test agent in water or air that produces 50% lethality over a defined period of time, a lethal concentration,  $LC_{50}$ . This approach remains in common use when studying aquatic organisms.

In modern toxicology, increasing attention is given to conducting studies with exposures that are defined by the anticipated conditions of use of the test material. This may involve initially conducting a study of 2 weeks' duration, perhaps with up to five exposure levels anchored by a level related to anticipated use. The results of this study are then used to select exposure levels, perhaps three or four, and to sharpen the focus of a 90-day study. The results of the 90-day study, in turn, are used to select the exposure levels and sharpen the focus of a study of 2 years' duration. Although it has become customary to conduct chronic exposure or 2-year studies with three exposure levels, it should be recognized that use of a control group and three exposure levels spanning a range of concentrations differing by a factor of 2, i.e., 1, 1/2 and 1/4 or a factor of 3, i.e., 1, 1/3, and 1/9, does not provide a robust data set for characterizing the shape of the exposure (dose)–response relationship. On the other hand, the use of exposure levels differing by a factor of 10, i.e., 1, 1/10 and 1/100 may provide an excessively broad range of exposure levels for identifying a lowest observed adverse effect level or no observed adverse effect level as will be discussed later.

In chronic studies, major attention is directed to evaluating any toxicant-induced changes in animals at the several exposure levels compared to controls over

a 2-year period or until a defined mortality level is reached, such as 20% surviving. Any changes in various indices of morbidity or pathological alterations will be evaluated compared to controls as well as tested for trends across the exposure levels. In many cases, the primary endpoint of concern will be cancer which should include evaluation of all stages of tumor development up to sarcomas and carcinomas. It has become customary to use life table statistical methods such as that of [Kaplan and Meier \(1958\)](#) to evaluate the incidence of key changes. This approach allows for the use of data not only from the survivors at the end of the study, but also animals that have died or been euthanized at interim times. This situation is analogous to that encountered in human epidemiological studies when subjects may be lost to follow-up.

It has become customary when the results of chronic studies will be used for regulatory purposes to convene a pathology peer review panel of expert veterinary pathologists, typically Diplomates of the American College of Veterinary Pathology (ACVP), to evaluate histological specimens from representative cases and the diagnoses of the original pathologist to verify that the diagnoses are appropriate and consistent with the scientific norm. As an aside, I encourage veterinary toxicologists to personally review the pathology findings in studies with the study pathologist so as to be familiar with the nature of the pathology findings. However, I discourage veterinary toxicologists from taking on a dual role of toxicologist and pathologist for a study. Indeed, this approach would be unacceptable for a study to be submitted for regulatory purposes unless the toxicologist was also an ACVP Diplomate.

### Describing exposure–response relationships for non-cancer endpoints

It is now appropriate to consider how the data generated from toxicological investigations can be used. Let us first examine a threshold exposure–response relationship as shown in [Figure 2.3](#) and shown now in an expanded form in [Figure 2.10](#). The first step is to examine the data set from critical exposure–response studies to identify key parameters to be used to describe the results. Key determinations are the no observed effect level (NOEL), the highest exposure level for which no effects are observed and the no observed adverse effect level (NOAEL), the highest exposure level that produces no adverse effects. Obviously, characterization of an effect as adverse or not adverse is a matter of professional judgment. For example, in a cholinesterase inhibitor study, is a reduction in blood cholinesterase in the absence of salivation or other clinical signs an adverse effect or merely an effect?

**FIGURE 2.10** Schematic rendering of a threshold–exposure response relationship.

In the absence of the identification of a NOAEL, there is a need to identify the lowest observed adverse effect level (LOAEL), the highest exposure level at which an adverse effect is observed. The specific NOAEL and LOAEL that can be identified are a function of the exposure levels originally selected for studies. To state the obvious, observations can only be made at the exposure levels studied. For example, if the exposure levels studied did not extend to a sufficiently low level, the lowest level might produce an effect thereby precluding observation of a NOAEL. Alternatively, the study might be designed with three exposure levels separated by a factor of 10 with the lowest exposure level identified as a NOAEL and the next higher exposure level identified as producing some modest adverse effects and, thus, identified as the LOAEL. In retrospect, in such a study it is not known whether the “true” LOAEL might have been a factor of three or five above the NOAEL since these levels were not investigated.

Another consideration is the nature of the effects identified at the NOAEL; was there evidence of enzyme induction or hyperplasia, hypertrophy or atrophy with no evidence of a change in organ weight? Likewise, at the LOAEL were hyperplasia, hypertrophy or atrophy present resulting in modest or substantial changes in organ and body weight? Were histological changes observed that were reversible? Were the changes sufficiently profound that the level would be identified as a functional effect level (FEL)? These questions serve to emphasize the extent to which professional judgment is involved in interpreting the results of all toxicological investigations.

For non-cancer effects a reference dose (RfD) for oral intake or an inhalation reference concentration (RfC) for airborne materials is calculated using the NOAEL or LOAEL as a starting point ([Jarabek et al., 1990](#); [Jarabek, 1994](#)). An RfD or RfC may be defined as an estimate (with

uncertainty spanning perhaps an order two magnitude) of a continuous oral or inhalation exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious non-cancer effects during a lifetime. The RfD and RfC values are developed from the experimentally determined NOAEL or LOAEL values as shown in Figure 2.10 (Jarabek, 1994) and normalized to continuous exposure. For a more complete description of the process, the reader is referred to a recent book chapter by McClellan *et al.* (2006). The EPA maintains an Integrated Risk Information System that includes comprehensive summaries of the toxicological information available on specific chemicals including RfD and RfC values and estimates of cancer-causing potency. These profiles are available online (EPA/IRIS, 2011).

A somewhat similar approach for non-cancer effects has been used by the American Conference of Governmental Industrial Hygienists (ACGIH) to develop threshold limit values (TLV) (ACGIH, 2011). A TLV is defined as airborne concentrations of substances that represent conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse health effects. Since the ACGIH TLVs apply to healthy workers they may not always incorporate a safety factor (SF) or uncertainty factor (UF) of 10 for human variability. The exposure duration for TLVs is based on a 40-hour/work week and, thus, the results of animal studies will be normalized to 40 hours/week.

The Agency for Toxic Substances and Disease Registry (ATSDR) develops minimal risk levels (MRLs) using a similar methodology. An MRL is an estimate of the daily human exposure to hazardous substance that is likely to be without appreciable risk of adverse non-cancer effects over a specified duration of exposure. For example, MRLs are derived for acute (1 to 14 days), intermediate (14 to 365 days) and chronic (365 days and longer) exposure durations. The MRLs are intended to serve as a screening tool to help public health professionals decide to look more closely at particular exposure situations. The ATSDR has prepared toxicological profiles on many chemicals including their MRLs. More than 200 profiles are available online (ATSDR, 2006).

The National Institute of Occupational Safety and Health (NIOSH) develops recommended exposure levels (RELs). RELs are set at levels such that virtually all persons in the working population (with the possible exception of hypersensitive individuals) would experience no adverse effects. The Occupational Safety and Health Administration (OSHA) sets permissible exposure levels (PELs) based on consideration of the NIOSH RELs. However, the OSHA values are legally enforceable limits unlike the NIOSH RELs which are guidance.

The International Programme on Chemical Safety (IPCS) prepares authoritative reviews on the environmental health impact of various chemicals. The reports

are available online (IPCS, 2011). The exposure limiting values developed by the IPCS are guidance values and not legally enforceable limits. The United States makes extensive use of legal enforceable exposure limits. Many other countries emphasize the use of guidance values. This distinction is important when comparing standards versus guidance originating from different countries.

In considering all of the foregoing guidance or regulatory levels, it is important to recognize that they are set to control exposures for workers or the general public. In each case, they are set to be health protective and, thus, are set at levels below where human effects have been observed or are expected to occur. These values should not be interpreted as being equivalent to levels producing adverse effects in humans.

### Cancer as an endpoint

For cancer as an endpoint, animal exposure-response studies may provide two kinds of input. First, the results may be used in carcinogen classification processes such as those of the International Agency for Research on Cancer, the EPA or NTP. As discussed earlier, these are hazard-based classification schemes – is a given agent capable of causing human cancer without consideration of the potency of the agent? These schemes have been described elsewhere (McClellan *et al.*, 2006; McClellan, 1999, 2010).

If a positive cancer outcome is observed in animal studies, the quantitative exposure-cancer response data may be used in a second way – to develop a risk coefficient, lifetime cancer risk per unit of exposure, for the potency of the agent for causing human cancer. Such extrapolations typically involve linear statistical extrapolations from high levels of exposure used in the animal studies to potential human exposure levels several orders of magnitude lower (recall Figure 2.3). In addition, they may purposefully be calculated based on the upper 95% confidence limit on some level of risk, for example, with a probability of a one in one million occurrence. In my opinion, these extrapolated values are highly uncertain. It is quite possible that for some agents classified as possibly or probably carcinogenic to humans in the absence of a positive association with cancer from epidemiological studies and, thus, based on high exposure-level animal study results, there is no added cancer risk at very low levels of exposure (Gold *et al.*, 2003). The EPA (2005a) has issued guidance for alternative approaches to estimate cancer risks when information is available on the mode of action of the agent, for example if the cancer arises as a result of the toxicity and secondary cell proliferation rather than a direct effect of the chemical or metabolite on DNA. For example, chloroform has been shown to cause cancer by this mode of action (Butterworth *et al.*, 1995). The EPA (2005b) has also provided guidance for considering the impact of susceptibility of early life exposures for causing cancer.

Information on the cancer-causing potential of various chemicals is included in the material summarized in the USEPA's Integrated Risk Information System ([EPA/IRIS, 2011](#)). The IARC monographs on the evaluation of carcinogenic risks to humans are all available online ([IARC, 2011](#)). The monographs cover the carcinogen classification reviews of over 800 compounds. The NTP publishes, on a biannual basis, a Report on Carcinogens. The 11th Report contained 246 entries, 58 of which were listed as "human carcinogens" with the remaining 188 being listed as "reasonably anticipated to be human carcinogens" ([NTP, 2005](#)). The potency of the various agents for causing cancer is quite varied. When examining this literature, many in the public, including some scientists, are surprised to learn how few agents have been conclusively identified as "human carcinogens." The facts stand in sharp contrast to the view conveyed in the popular media and some scientific publications that people live in a "world of carcinogens."

### New potential endpoints

In recent years, the expansion of knowledge at the molecular and cellular level has provided the opportunity for considering the addition of a myriad of new endpoints to toxicological evaluations. This includes an array of new molecular biomarkers which have received substantial attention. Although biomarkers are frequently discussed as new approaches, it is well known to the veterinary clinician and toxicologist and to physicians that biomarkers have been used in both human and veterinary medicine for centuries.

In some cases, measurement of the biomarkers present in body fluids, urine or exhaled breath serve as an indicator of exposure or, even, dose of a toxicant. Recall the report of the individual arrested for "driving while intoxicated" based on a breathalyzer test for exhaled alcohol which has been converted to a blood alcohol level. In other cases, the biomarker is an indicator of a disease process. Recall individuals being evaluated for prostate cancer based on an elevated level of prostate-specific antigen in serum samples.

New biomarkers of exposure will continue to be proposed. For each potential biomarker of exposure, it will be necessary to conduct experiments to validate the utility of the biomarker. A special challenge relates to recognizing the dynamics of the toxicokinetics of various toxicants and establishment of quantitative relationships between exposure and dose at any particular time over the course of the intoxication.

The potential list of biomarkers for toxic responses is seemingly endless. In all fields of medicine, from different kinds of cancer to various functional diseases of every organ system, new molecular markers are being

identified on a regular basis. The challenge for toxicologists is to consider from among this array of opportunities which biomarkers are sufficiently well validated with regard to their linkage to diseases and sufficiently reasonable in cost to warrant their use in exposure-response studies. This includes consideration of the new and highly sophisticated genomic tools. There is a special challenge in designing validation studies to make certain that the experimental design is directed toward identifying specific disease-related endpoints or toxicant-related effects rather than merely being another, albeit more sophisticated, marker of non-specific toxic effects. A serious issue in many previous validation studies has been the use of a single high exposure level and a few short-term observation times. Such studies are unable to evaluate exposure-related changes in biomarkers and may not be able to identify toxicant-specific changes.

Two recent reports prepared by Committees of the National Research Council provide insight into how some individuals envision the future of toxicity testing. The first [NRC Report \(2007a\)](#) addresses the application of toxicogenomic technologies in predictive toxicology and risk assessment. The second [NRC Report \(2007b\)](#) provides a strategy and vision for toxicity testing in the 21st century. I encourage veterinary toxicologists, whether they are in training or experienced, to carefully read these reports. I view both of the reports as aspirational. In my opinion, both committees would have benefited from participation by veterinarians who understand the complexity of disease processes and toxicoses to counterbalance the views of molecular and cell biologists who focus on the micro-level and systems biology and may overstate the role of mathematical models. The concept of systems biology has come to the forefront in recent years. In my view, the concept of a systems approach to normal biology and disease processes has been a fundamental concept undergirding both veterinary medicine and human biology for more than a century.

## CONCLUSIONS AND SUMMARY

Veterinary toxicology is a multi-faceted hybrid that draws on and contributes to the veterinary medical profession, the scientific field of toxicology and, broadly, to medical science. Some have characterized toxicology as a distinct scientific discipline. I view toxicology as an applied area of science addressing important societal issues by drawing on multiple scientific disciplines and professions. Veterinary toxicology, as a sub-specialty in veterinary medicine, had a very applied origin – the diagnosis and treatment of toxicoses in domestic animals and companion animals. That important role continues

today. However, the field has broadened to include concern for contaminants in human food products originating from animals and for contributing to the conduct and interpretation of safety/risk evaluations for pharmaceuticals, food additives, consumer products and specific chemicals. Veterinary toxicologists who understand both normal and disease processes extending from the molecular level to the integrated mammalian organism and, indeed, populations, have an array of opportunities for making significant contributions to society. The prospects for the future of veterinary toxicology and the opportunities for veterinary toxicologists have never been brighter.

## DEDICATION

This chapter is dedicated to the memory of Charles C. Capen (1936–2008), an internationally recognized comparative pathologist and endocrine toxicologist. A complete obituary was published in *Toxicologic Pathology* (Anonymous, 2008). Chuck and I were classmates in the College of Veterinary Medicine at Washington State University receiving our Doctor of Veterinary Medicine degrees in 1960. Chuck immediately entered the residency and graduate program in Veterinary Pathology at the Ohio State University (OSU). He received his Ph.D. from OSU in 1965 and soon passed the certifying examination of the American College of Veterinary Pathologists (ACVP) and became an ACVP Diplomate. He progressed rapidly through the academic ranks becoming a full professor and, ultimately, a distinguished university professor. He provided outstanding leadership as chairperson from 1981 to 2002 of the OSU Department of Veterinary Biosciences. He was an outstanding teacher and researcher. One of his major contributions was in the interpretation of endocrine system effects observed in laboratory animal species as to their significance as predictors of human disease for various chemicals, including candidate pharmaceuticals. His special expertise resulted in his being asked to serve on many advisory committees and as a consultant to many companies around the globe. He was an elected member of the Institute of Medicine of the National Academy of Science and a recipient of many other honors.

## ACKNOWLEDGMENTS

Many of the concepts presented in the chapter are based on my experience working with talented scientists at three institutions; the Hanford Biology Laboratory at Richland, WA, the Lovelace Inhalation Research Institute (now a part of the Lovelace Respiratory Research Institute) in Albuquerque, NM, and the Chemical

Industry Institute of Toxicology (now the Hamner Institutes Health Sciences) in Research Triangle Park, NC. Moreover, my insights into the basic concepts of toxicology have been sharpened by my experience serving as an advisor on toxicology and human health risk issues to public agencies and private clients and the opportunities I have had for working with many outstanding toxicologists and other scientists.

The excellent assistance of Mildred Morgan in preparing this chapter and the useful review comments of Drs. Ramesh C. Gupta, Fred W. Oehme and Mike Murphy on an early draft are gratefully acknowledged.

# Toxicokinetics

*Deon van der Merwe, Ronette Gehring and Jennifer L. Buur*

## INTRODUCTION

The epithelial barriers that form the body's interface with the environment, and the cellular barriers that separate internal organs and tissues, have to be permeable to a wide variety of chemicals to allow nutrient absorption and waste product elimination. The permeability of these physiological barriers, however, also allows toxicants to penetrate. Exposure to toxicants through ingestion, inhalation, and dermal contact may therefore result in harmful absorption. The degree of adverse effects following exposure to a toxicant is dependent on the rate and extent of absorption into the body, distribution to susceptible organs and tissues, and specific interactions with biological targets. Living organisms are adapted to toxicant exposure through the development of transport and elimination mechanisms that prevent the build-up of harmful chemical concentrations in organs and tissues.

Toxicokinetics refers to the movement and fate, also referred to as the disposition, of toxicants. The term is most commonly used when describing the time course of absorption, distribution, and elimination (including biotransformation and excretion) of toxicants in an organism. Toxicokinetics is closely related to pharmacokinetics, and may even be viewed as the same discipline, with the only difference being the class of compound (toxicant or pharmaceutical) that is involved. Compared to typical pharmaceutical exposure, exposure to toxicants is often uncontrolled and variable, and very large doses may be involved. Toxicants are also more likely to cause lesions and abnormal physiological function that may alter the toxicant disposition, compared to exposures to pharmaceutical drugs below toxic levels. When very large doses are involved, kinetic

processes that can become saturated are more likely to reach their maximum rates, resulting in altered disposition.

Predicting tissue concentrations over time is essential for the prediction of adverse effects ([Andersen \*et al.\*, 2006](#)). It is also needed to prevent unwanted xenobiotic residues in animal tissues from entering foods of animal origin. Kinetic parameters, such as duration of internal exposure and tissue concentrations, are therefore useful metrics for assessing risk. Mathematical models are used to characterize these parameters by describing changes in toxicant concentrations over time. Models are most often used as predictive tools following exposure to toxicants, but they can also be used as an aid to understanding the underlying physiological mechanisms of chemical absorption, transport and elimination. Various types of toxicokinetic models have been developed and the appropriateness of a specific model type depends on the available data and the model's purpose (Riviere, 2011). One of the key challenges to the successful use of models is identifying the appropriate conditions for its application. Two fundamentally different types of toxicokinetic models are recognized: traditional (also called "classic") toxicokinetic models and physiologically based toxicokinetic models. Traditional toxicokinetic models are mathematical descriptions of concentration/time profiles that are constructed without assuming that the compartments and functions used in the models are directly representative of physical structures or physiological processes. The selection of compartments and functions are therefore solely dependent on their ability to simulate experimentally observed concentration/time profiles. Physiologically based toxicokinetic models, on the other hand, are mathematical simulations of kinetic processes in organs and tissues. The mathematical constructs therefore represent actual organs, tissues and physiological processes.

## UNDERLYING PHYSIOLOGY

### Absorption

Most hazardous substances must gain access to the systemic circulation to exert their toxic effects through interaction with one or more internal organs. Notable exceptions are those compounds that cause a local reaction at the site of exposure. Absorption is the process whereby toxic substances gain entrance to the body from the external environment by crossing cellular barriers. The primary routes of exposure for toxic substances are oral, respiratory, and dermal.

The gastrointestinal, respiratory, and dermal systems are lined with epithelia that present significant barriers to the entry of foreign substances due to tight junctions between their cells, or continuous lipid layers in the case of skin. The membranes of cells that form viable epithelial barriers are traversed by transporter proteins that either actively exclude xenobiotics, or facilitate the movement of specific substrates across the barrier. The onset, duration and intensity of a substance's toxic effects are therefore dependent on the toxicant's ability to permeate lipid cell membranes directly, and its interactions with transporter proteins. Dermal penetration is unique in the sense that the outer epithelial cellular layers (corneocytes) are non-viable and do not contain transporter proteins. Absorption, in this case, is therefore dependent on the ability of toxicants to penetrate the intercellular lipid matrix found between corneocytes. There are several factors that may influence the permeability of epithelial barriers to specific xenobiotics, including the physicochemical properties of the substance, blood supply at the site of exposure, and the concentration of the substance at the site of contact. A specific compound may be categorized as relatively non-toxic by one route and highly toxic via another due to differences in absorption from these sites.

### Distribution

Distribution is the process whereby toxicants move throughout the body and reach their site of action. Once absorbed, a toxicant typically enters the interstitial fluid at the site of absorption and then passes into the tissue cells or enters the blood and/or lymph. Blood is moved rapidly through the body by the cardiovascular circulatory system and this process constitutes the major mechanism whereby absorbed chemicals are distributed to the various organs and tissues of the body.

To be distributed through the body by the cardiovascular system, a toxic chemical must first cross the capillary endothelium, and then diffuse through the interstitial fluid and penetrate the cells of the target

organ. The entrance of xenobiotics to some tissues is restricted by special barriers (e.g., blood–brain barrier, blood–testes barrier and blood–placenta barrier) that form continuous cellular layers with tight junctions that prevent movement of toxicants into tissues by passive diffusion through intercellular spaces. To gain entry into these protected tissues, toxicants must pass through lipid cell membranes, either by penetrating the lipid membranes directly, or by active or facilitated transport through transmembrane transporter proteins. Factors that determine a compound's rate and extent of distribution therefore include molecular size, lipophilicity, plasma protein binding and the ability to interact with transmembrane transporter proteins. Uneven distribution through the body may occur due to affinity for specific environments such as fat for highly lipophilic compounds or bone for compounds that bind to  $\text{Ca}^{2+}$ . This can lead to extremely low concentrations in the blood plasma and accumulation with prolonged storage of the compound at the depot sites.

### Biotransformation

Biotransformation is a key body defense mechanism whereby chemical reactions transform xenobiotic compounds in the body. The major transformation reactions for xenobiotics are divided into two phases. Phase I reactions (oxidation, reduction, hydrolysis and acetylation) modify the compound's structure by adding a functional group. This allows the substance to interact with Phase II enzymes, which conjugates it with a water soluble molecule such as sulfate, glucuronide, glutathione and amino acid. The water solubility of a compound is typically increased by this process, and it is an important step towards the excretion of lipid soluble toxicants. Water soluble compounds that are small enough to pass through the renal glomerulus can usually be excreted relatively rapidly through the urine without biotransformation. Biotransformed toxicants will often have reduced toxicity compared to the parent compounds. In some cases, however, biotransformation increases toxicity. Biotransformation enzymes have broad substrate specificity. They are, therefore, able to transform a wide range of substrates.

### Excretion

One of the primary mechanisms of protecting the body from the toxic effects of toxicants is the elimination of these compounds from the body. Compounds that are rapidly eliminated are less likely to accumulate in tissues and damage critical cells. Although the terms elimination and excretion are sometimes used synonymously, the former term encompasses all the processes that

decrease the amount of parent compound in the body, including biotransformation. Excretion is the term used specifically to refer to the processes by which toxic compounds leave the body through excretory organs. The main routes of elimination are urine, feces and exhaled air. Except for the lung, water-soluble substances are more readily excreted because they are not readily reabsorbed through cellular barriers in the excretory organs.

## TRADITIONAL (COMPARTMENTAL) TOXICOKINETIC MODELS

### Introduction

Traditional compartmental pharmacokinetic models describe the aggregate result of all the processes involved in determining the concentration/time curve of a compound in a reference compartment, which is most often the venous blood, and referred to as the central compartment. It uses single or multiple compartments and first-order rate equations, chosen to optimally describe experimental data, with no direct physiological relevance or fidelity to anatomical structure or physiology. The main use of these models is to predict plasma concentrations in exposure conditions that are similar to the conditions under which the data were produced from which the model was derived. Traditionally, exponential equations have been used to quantitatively describe the changes in concentrations of toxic substances in plasma and tissue over time Eqn (1) (Gibaldi and Perrier, 1982; Rivere, 2011).

The following is a typical bi-exponential equation used to describe time/concentration data of xenobiotics in plasma:

$$C(t) = Ae^{-\alpha \times t} + Be^{-\beta \times t} \quad (1)$$

where  $C(t)$  is the xenobiotic concentration at time  $t$ ,  $\alpha$  and  $\beta$  are the slopes of the two phases with different disappearance rates and  $A$  and  $B$  are their intercepts with the  $y$ -axis.

In these models, the body is viewed as comprising one or more “equilibrium compartments,” from which the toxic compound disappears at the same rate. These abstract compartments are not ascribed to specific organs or regions of the body, but are understood to encompass a collection of tissues with similar blood supply and affinity for the compound of interest. The number of exponential terms in these traditional compartmental kinetic models therefore reflects the number of kinetically homogeneous compartments, with an additional term added to account for absorption if exposure is extravascular. These exponential equations

then serve as the basis to calculate physiologically relevant pharmacokinetic parameters that reflect the various kinetic processes ( $V_d$  = volume of distribution;  $CL$  = clearance). The equations are also used to predict plasma concentrations for different exposure scenarios.

The most common models used to describe plasma time/concentration profiles of xenobiotics are the one- and two-compartment open models. The one-compartment model describes the profile of a compound that distributes instantaneously and evenly in the body and is eliminated at a rate that is proportional to the amount left in the body. On a semi-logarithmic scale, plasma concentrations of these compounds decline linearly over time (Figure 3.1). For other compounds, an additional compartment (exponential term) must be added, because the plasma concentrations decline in two phases, with the decline during the first phase typically being more rapid than during the second phase (Figure 3.2). Concentrations of these compounds in the second compartment rise, peak and subsequently decline over time as the substance is eliminated from the body.

This approach to toxicokinetic modeling assumes that absorption, distribution, metabolism and excretion occur

FIGURE 3.1 First order decline in plasma concentrations on a semi-logarithmic scale, according to a one-compartment model.

FIGURE 3.2 Plasma concentrations according to a two-compartmental model, demonstrating the separate contributions of two compartments to the rise and decline in blood concentrations.

at rates that are directly proportional to the concentration of the toxicant (i.e., that they are first-order kinetic rate processes). It is important to realize that this assumption does not always apply for toxic compounds, particularly at high concentrations when the transporters and the enzymes that facilitate these processes become saturated. This means that, in the absence of evidence showing that the system maintains linear, first-order kinetics over the range of concentrations that are of interest, the values of kinetic parameters should be interpreted with caution and cannot be used to extrapolate to higher or lower doses.

## Measures of absorption

Often, only a fraction of the total dose to which an animal or human is exposed gets absorbed systemically. This fraction is referred to as the bioavailability ( $F$ ) and is calculated by comparing the areas under the plasma time/concentration curves for the toxic compound administered intravenously versus the typical route of exposure. These data are not readily available for most toxic compounds, although the relative bioavailability from different routes (e.g., oral versus dermal) is often known. Other measures of the rate and extent of absorption include the absorption rate constant ( $k_a$ ), maximum measured concentration in the plasma ( $C_{\max}$ ) and time after exposure when this concentration is measured ( $T_{\max}$ ).

## Volume of distribution

The total volume of fluid in which a toxic substance must be dissolved to account for the measured plasma concentrations is known as the apparent volume of distribution ( $V_D$ ). If a compound is distributed only in the plasma fluid, the  $V_D$  is small and plasma concentrations are high. Conversely, if a compound is distributed to all sites in the body, or if it accumulates in a specific tissue such as fat or bone, the  $V_D$  becomes large and plasma concentrations are low. The value of this parameter is calculated from the multi-exponential equation that is fitted to the data using:

$$V_D = \frac{\text{Dose}}{\sum_{i=1}^n C_i} \quad (2)$$

which is the calculation of apparent volume of distribution from traditional pharmacokinetic parameters where  $C_i$  refers to the intercepts of the various phases of the curve with the  $y$ -axis.

## Clearance

Total body clearance ( $CL$ ) is the pharmacokinetic parameter that reflects the body's inherent ability to eliminate

a xenobiotic through organs of elimination. The value of this parameter represents the volume of blood cleared of the toxic substance per unit of time. If the total absorbed dose is known,  $CL$  can be calculated using Eqn (3). Many times the absorbed dose is not known, and the calculated value of this parameter reflects not only  $CL$  but also an unknown value for bioavailability ( $F$ ). The lower  $F$ , the higher the calculated value for a specific dose will be:

$$CL = \frac{\text{Dose}}{AUC_{0-\infty}} \quad (3)$$

which is the equation used to calculate total body clearance, where  $AUC_{0-\infty}$  is the area under the plasma time/concentration curve extrapolated to infinity.

## Half-life

A compound's half-life in plasma ( $T_{1/2}$ ) is a composite parameter that is dependent on both the body's inherent ability to eliminate the compound ( $CL$ ), as well as the extent to which the compound is distributed through the body ( $V_D$ ). This relationship is illustrated in the following equation:

$$T_{1/2} = \frac{0.693 \times V_D}{CL} \quad (4)$$

which represents widely distributed compounds due to their low concentrations in plasma (assuming first-order kinetics, where the rate of elimination is proportional to the amount of drug presented to the eliminating organ).

## Flip-flop kinetics

Flip-flop kinetics refers to a situation when the rate of absorption of a compound is significantly slower than its rate of elimination from the body. The compound's persistence in the body therefore becomes dependent on absorption rather than elimination processes (Figure 3.3). This sometimes occurs when the route of exposure is dermal.

## Residues

An additional concern with food-producing animals is the potential for adverse effects in the human consumer if edible tissues harvested from exposed animals contain harmful residues of toxic compounds. Tolerances (also known as maximum residue levels in countries other than the U.S.) are legal limits of allowable concentrations to prevent harm in consumers from toxic compounds in foods. The length of time following exposure required

**FIGURE 3.3** Plasma concentrations comparing a slow rate of absorption to a rapid rate of absorption, demonstrating “flip-flop” kinetics, where persistence of the compound is dependent on the rate of absorption, rather than the rate of elimination.

for concentrations in animal tissues to deplete to levels that are below these tolerances is referred to as the withdrawal time. The length of these withdrawal times are closely related to the compounds’ rates of elimination, and therefore their half-life, in the specific tissue of interest. It is important to note that the tissue depletion rate is unlikely to be the same as the rate of depletion from plasma, although the two are often related.

## PHYSIOLOGICALLY BASED TOXICOKINETICS

### Introduction

Physiologically based toxicokinetic (PBTK) models are mathematical simulations of physiological processes that determine the rate and extent of xenobiotic chemical absorption, distribution, metabolism and excretion. Such models can be used for predicting internal doses at target organs and tissues due to their conformity to actual organs, tissues and physiological processes. Internal dose predictions are useful for dose–response analyses and risk assessment involving specific mechanisms and sites of toxicity. Successes in the application of PBPK models to predict xenobiotic concentrations at target sites have led to its acceptance as a modeling technique in risk assessments. It is also used in mechanistic studies of the underlying processes that determine pharmacokinetic profiles and dose–response relationships.

In veterinary toxicology, PBPK methods can be used to improve the accuracy of predictions of toxicity across species by applying data obtained in one species to predictions in another species. It can be used to predict the effects of changes in physiological conditions, environmental conditions, activity levels and pathological

changes on xenobiotic concentrations in target tissues. This allows for more accurate assessment of risk in varied individual animals and populations. PBPK approaches can be used to study and understand the effects of mechanisms that determine the internal exposure of animals to potential toxins – such as dermal absorption and xenobiotic metabolism. PBPK models can also be used to address problems associated with the exposure of food producing animals to drugs and chemicals that may result in potentially harmful or undesirable residues in meat, milk and other foods of animal origin (Brocklebank *et al.*, 1997; Craigmill, 2003; Buur *et al.*, 2005).

PBPK models also make use of compartments, but in contrast to traditional compartmental models, the compartments are derived from mathematical descriptions of physiological body compartments or tissues. Links between the compartments simulate physiological processes of partitioning, transfer, metabolism and excretion. If the compartments and kinetic processes are accurately described, the concentration/time curves of chemicals in specific organs and tissues can be estimated. This offers an advantage over traditional compartmental models, because differences in physiology, anatomy, environment, metabolism and the effects of chemical-induced physiological changes and pathology can be simulated. Parameters can be scaled to reflect different dose ranges, species, breeds, genetic polymorphism and life-stages. The advantages of PBPK models are, however, difficult to achieve because the necessary anatomical and physiological parameter values are often not known, and/or the relevant pharmacokinetic processes are not well understood. The completeness of PBPK models depends entirely on the completeness of knowledge of the modeled system, and complete models are not attainable in most situations. PBPK models tend, therefore, to be simplified representations of reality based on assumptions regarding the most important processes and structures that determine the pharmacokinetic profile of the chemical in question.

Typical PBPK models simplify the body and represent it as a series of well-stirred compartments representing major organs and tissues of interest, a single dose and route of exposure, and the major route of excretion. The compartments are linked by blood flow, and the movement of chemicals between compartments is determined by tissue/blood partitioning and blood flow rates. However, when enough data are available, highly detailed, multiple compartment models can be constructed that include complete dosing regimens or exposure scenarios, detailed organ structures and physiological processes, as well as specific processes of metabolism, and simulations of metabolite pharmacokinetics. Models of varying complexity focusing on specific organs and routes of absorption/elimination, such as the skin and respiratory organs, have also been developed (Andersen *et al.*, 2002; Frederick *et al.*, 2002; Van der Merwe *et al.*, 2006).

## Model construction

The first step in the construction of a PBPK model is determining the purpose of the model and what internal tissue doses are needed to answer the specific scientific questions being asked. Once that is done, a schematic diagram is constructed that consists of each of the tissue compartments of interest, a plasma compartment, and a compartment or compartments that represent the rest of the physiological system. It is often necessary to include more than one compartment to represent the remaining portions of the body to reflect the differences in high and low blood flow tissues. The compartments can be subdivided into extracellular and intracellular spaces (Colburn, 1988). Tissue blocks and their sub-compartments can be combined to make the model as simple or as complex as needed. A schematic diagram for a generic whole body model is shown in Figure 3.4. Figure 3.5 depicts a generic tissue block with sub-compartments as well as possible binding sites and sources of elimination. In contrast to the full body model, Figure 3.6 presents a schematic diagram used in the prediction of sulfamethazine (SMZ) tissue residues in swine (Buur *et al.*, 2005). This model contains several simplifications, including a reduced number of tissue blocks, and the combination of tissue blocks into a single compartment. Because the model was designed to predict SMZ residues in edible swine tissues, only the edible tissues were specifically included in the model. The rest of the body was lumped into a single tissue block. Elimination is by renal filtration and is schematically represented using arrows that are not directed into the plasma compartment. The main metabolite is also modeled, and the two xenobiotics are linked together via the liver tissue block. This is an example of how model complexity can be optimized to achieve specific aims.

Following a schematic design of the model, the model is described using mass balance equations that represent the changes in tissue concentrations over time. The limiting factor in the exchange between compartments is an important consideration. In most models, the exchange is either limited by diffusion through a membrane barrier (diffusion-limited), or it is limited by the amount of blood flow (flow-limited). Both types of exchanges may be present in a single PBPK model. Diffusion-limited exchanges are often associated with large, polar molecules, and organs with small blood flow to mass ratios. Flow limited exchanges are most commonly associated with small, lipophilic compounds, and organs with relatively small volume and large blood flow to mass ratios.

The basic mass balance equation for a flow-limited compartment is:

$$V_t dC_t/dt = Q_t(C_a - C_v) \quad (5)$$

where  $Q_t$ ,  $V_t$  and  $C_t$  are the blood flow, anatomic volume, and concentration of the compound in the compartment,

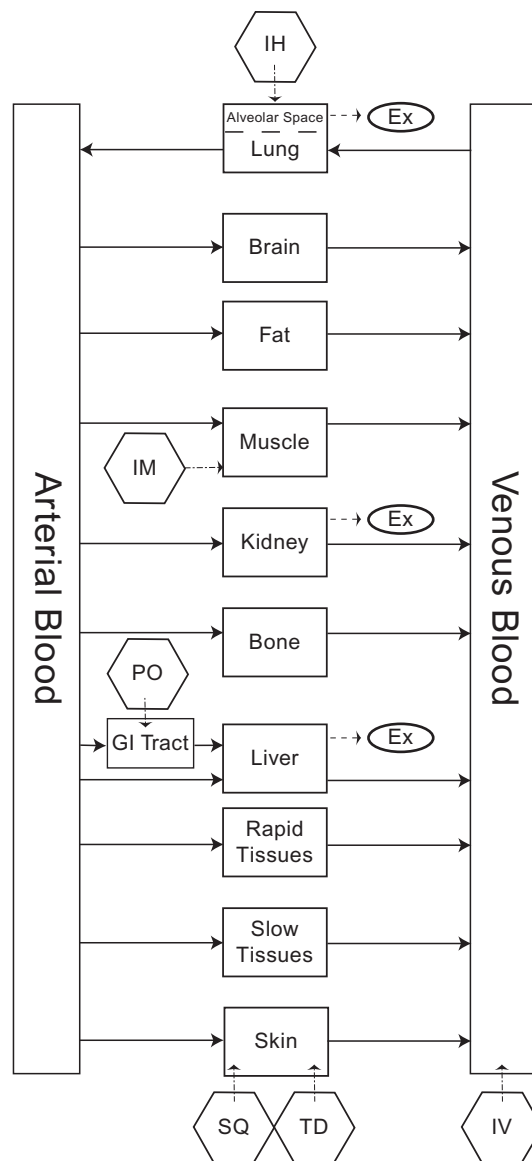

FIGURE 3.4 Schematic diagram of a generic whole body physiologically based pharmacokinetic model.

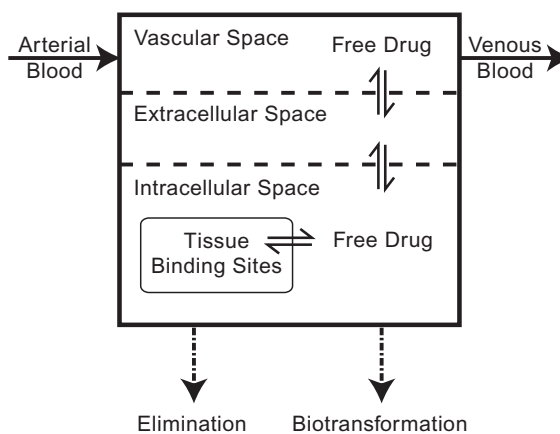

FIGURE 3.5 Schematic diagram of a generic tissue block physiologically based pharmacokinetic model, with sub-compartments as well as possible binding sites and sources of elimination.

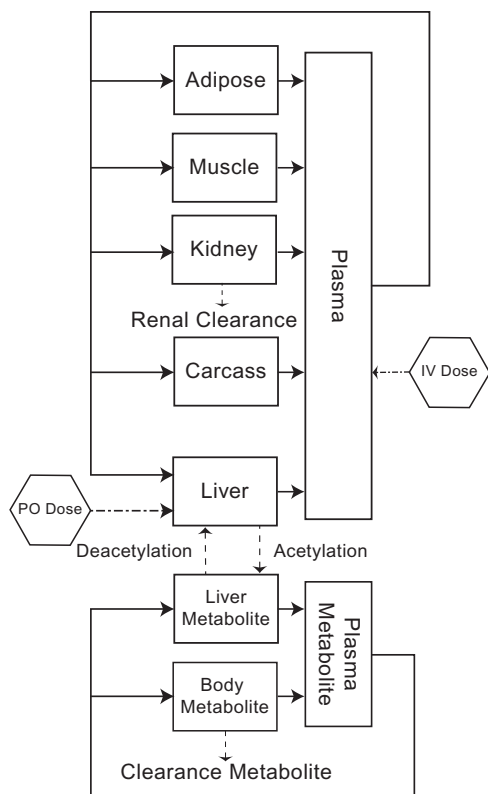

FIGURE 3.6 Schematic diagram of a physiologically based pharmacokinetic model, used in the prediction of sulfamethazine tissue residues in swine.

and  $C_a$  and  $C_v$  are the concentrations of the compound in the arterial and venous blood flowing into and out of the tissue. It is assumed in flow-limited models that the compound is in instantaneous equilibrium between the tissue and the blood, and that distribution in the compartment is homogeneous. This allows for the relationship between the venous blood concentration and the vascular space to be defined according to the partition coefficient between the tissue and blood:

$$C_v = C_t/P_t \quad (6)$$

where  $P_t$  is the tissue-to-blood partition coefficient. Therefore, the final mass balance equation is:

$$V_t dC_t/dt = Q_t(C_a - C_t/P_t) \quad (7)$$

This equation can be used in models where all tissue compartments are simplified into a single compartment. In contrast, membrane-limited exchanges do not assume that tissue concentrations are in equilibrium with venous blood concentrations. Instead, it uses sub-compartments representing extravascular and intracellular space. The assumption is that the vascular space is in equilibrium with the extracellular space. The mass balance equation

is then defined by rate of change in the extracellular space per unit of time, and can be written as:

$$\begin{aligned} V_e dC_e/dt &= Q_t(C_a - C_e) - K_t(C_e - C_i) \\ V_i dC_i/dt &= K_t(C_e - C_i/P_t) \end{aligned} \quad (8)$$

where  $V_e$  and  $C_e$  are the anatomic volume and concentration in the extracellular space,  $V_i$  and  $C_i$  are the volume of the intracellular space and the concentration in the intracellular space, and  $K_t$  is the membrane permeability coefficient for the membranes that separate the intracellular and extracellular spaces.

Further modifications are needed to describe metabolism or excretion. This can be done by adding a mass removal term,  $R_{ex}$ . The resulting equation for a flow-limited tissue block is:

$$V_t dC_t/dt = Q_t(C_a - C_t/P_t) - R_{ex} \quad (9)$$

The mathematical definition of  $R_{ex}$  can be as simple or as complex as needed to describe the important features of the process. Commonly used functions include simple first-order exchanges, and Michaelis-Menton equations that describe processes that can become saturated. For example, if  $R_{ex}$  is defined as the clearance of a specific organ the equation would be:

$$V_t dC_t/dt = Q_t(C_a - C_t/P_t) - C_t Cl_{organ} \quad (10)$$

where  $Cl_{organ}$  is the clearance of the eliminating organ.

Tissue blocks can be further refined by the addition of modification terms to describe processes such as protein binding, tissue binding, active transport, biliary excretion, enterohepatic circulation, and metabolism. For example, if  $R_{ex}$  is governed by metabolism, and the appropriate parameter values of enzyme activity are known, it can be described using Michaelis-Menton equations such as:

$$R_{ex} = (V_m f_1)/(K_m + f_1) \quad (11)$$

where  $V_m$  is the maximum rate of metabolism,  $K_m$  is the concentration at which the rate of metabolism is 50% of maximum, and  $f_1$  is the free concentration in the metabolizing organ. The final step is to write the mass balance equation for the central (venous blood) compartment. The input into this compartment is the combined venous blood streams from the various tissue compartments. The rate of change in concentration in the central compartment is described by:

$$V_p dC_p/dt = \sum Q_t C_v - Q_p C_p \quad (12)$$

where  $V_p$ ,  $Q_p$ , and  $C_p$  are the anatomic volume, the total blood flow, and the concentration in the central

**FIGURE 3.7** A comparison of the relative contributions to plasma disposition from the parameters of renal clearance, hepatic clearance, and tissue partitioning coefficients.

compartment, and  $C_v$  represents the venous blood concentration from each tissue compartment. As with other compartments, this compartment can be modified to incorporate processes such as protein binding, or partitioning into blood cells.

### Parameter estimation and identifiability

Accurate parameter values are essential for PBPK models to achieve their full predictive potential. The relevant parameters are often physiological (blood flow, organ volume, vascular space volume, etc.), and physicochemical (partitioning coefficients, membrane permeability coefficients, rate of absorption, etc.). Some parameter values can be estimated from *in vitro* experiments (protein binding rates, Michaelis-Menton constants, etc.). Many parameter values can be found in the published literature. Some parameters can be derived from *in vitro* and *in vivo* experimentation. However, there will usually be some parameters for which independent values cannot be obtained. These parameter values must be estimated using a curve-fitting process against known data points (Sheiner, 1985). Several curve-fitting software packages are available. Most use a function of a least likelihood ratio to estimate the parameters. It is important to emphasize that a weakness of PBPK models is their dependence upon a large number of parameters. The large numbers

of parameters can also make identifiability challenging. Identifiability refers to the ability to specifically determine a unique influence on model output for each parameter, based on an ideal data set. As the number of tissue compartments increases, the ability to uniquely identify all parameters is diminished without the inclusion of additional data points. Valid inferences cannot be drawn from a model if the model contains unidentifiable parameters. To reduce the likelihood of this type of error, multiple tissue compartments may be sampled. Thus, it is not only the number of data points representing the final model output that are used, but also the number of sampled compartments that is important for accurate parameter estimation (Audoly *et al.*, 2001). Identifiability problems can also be reduced by decreasing the number of parameters that need to be estimated. Sensitivity analysis can be used to decide which parameters can be abandoned without significantly altering model output. It compares the relative contributions of reasonable ranges of parameter values to an output of interest (Evans and Andersen, 2000). For example, in the SMZ model example, the relative contributions to plasma disposition from the parameters of renal clearance, hepatic clearance and tissue partitioning coefficients can be compared (Figure 3.7). The parameters of protein binding, hepatic clearance and renal clearance have the greatest effect at early time points.

The range of parameter values to use can be estimated using statistical distributions rather than fixed ranges.

**FIGURE 3.8** A Monte Carlo analysis using a physiologically based pharmacokinetic model, used in the prediction of sulfamethazine tissue residues in swine, to simulate multiple oral dosing.

As with single point estimations, the accuracy of the model is directly proportional to the accuracy of the distribution. In many cases, a reasonable mean and range of parameter value distribution can be inferred from published data. Distribution patterns can also be assumed to follow a model commonly found in natural systems (normal, log-normal, beta, etc.).

## Model validation

Model validation refers to the process of confirming that the model actually achieves its intended purpose. In most situations, this will involve confirmation that the model is predictive under the conditions of its intended use. This type of validation occurs by comparing model simulations to an independent experimental data set. Data used in the estimation of model parameter values cannot be included in the external data set. Simulated data derived from the model are compared to observed data points. The sets of data may be plotted side by side using simulation plots; or output values at specific times can be compared using correlation plots and residual plots. Results are then subjected to qualitative and quantitative analysis for goodness of fit. Unlike traditional compartmental pharmacokinetic modeling approaches, there is currently no standardized method to evaluate the goodness of fit for PBPK models. Often, a combination of visual examination of residual plots and simulation plots, along with the quantification of regression correlation values ( $R^2$  values), are used. In general, residual plots should have normal distributions around zero without

any time bias. Correlation plots should have regression lines with  $R^2$  values close to 1, and intercepts close to the starting value (in most cases, this is zero). Simulation plots are also used to detect time and concentration bias.

If a complex model was created by the incorporation of population distributions, then model validation typically becomes more qualitative in nature. In these cases, sampling methods such as Monte Carlo or bootstrapping can be used to generate specific values for the parameters in question. This parameter value assignment is repeated a large number of times, and the output becomes a set of simulations that can be plotted alongside each other. This gives a visual representation of what a population may look like (Sweeney *et al.*, 2001). Figure 3.8 shows a Monte Carlo analysis using the SMZ model to simulate multiple oral dosing (Buur *et al.*, 2006). The oral absorption rate, rate of gastric emptying, protein binding, and both renal and hepatic clearances were varied. Validation of these data is performed by plotting the multiple simulations alongside independent experimental data points. However, confidence in the distributions and in the model is determined by visual inspection, rather than correlation coefficients or residual plots. Generally, more data points covered within the spread of the output results in higher confidence in the predictive ability of the model.

## Applications

PBPK models are most often used in toxicology to predict the concentrations of toxic chemicals and their

**FIGURE 3.9** Schematic diagram of a physiologically based pharmacokinetic model used to describe the trans-dermal absorption of organophosphate insecticides in flow-through diffusion cells.

metabolites in target tissues. Target tissue concentrations predict toxic effects better than exposure concentrations or concentrations in a reference compartment such as venous blood. The adaptability of PBPK models makes them suitable for extrapolations across different exposure scenarios and routes, species, breed, age, physiological state, pathological changes and sex differences. PBPK models are also used in basic research to understand the effects and interactions between anatomical structure, tissue composition and physiological processes that influence the concentration/time course of xenobiotic chemicals. Toxicologists are often faced with situations where the adverse health risk from chemical exposure must be estimated without access to data obtained under the conditions of the exposure being analyzed. An advantage of well-designed, appropriately detailed and adequately understood PBPK models is that different exposure scenarios can be simulated using the same base model by varying the mathematical descriptions of the dosing regimen. These may include single, repeated or continuous oral ingestion, single or repeated intravenous boluses, constant intravenous infusion, single or repeated injections at various body sites, inhalation and topical exposures under various conditions. As long as the influences of dependent parameters on the reference concentration/time curve can be reliably identified, the model can be used to simulate the effects of variations in parameter values. It can also be used to do limited hypotheses testing related to key parameters. An example of this approach is the use of a PBPK model to describe the transdermal absorption of organophosphate insecticides in flow-through diffusion cells (Figure 3.9) (Van der Merwe *et al.*, 2006). Detailed independent parameter estimations, in a relatively simple physiological system, reduced the dependent parameters to three – each with an identifiable influence on the concentration/time

curve in the receptor chamber of the flow-through cell. Sensitivity analyses were used to identify important parameters and to generate hypotheses regarding the effects of changes in the skin related to those parameters. This approach can be used to discover important parameters *in silico*, which can be used to generate testable hypotheses. For example, the number of cell layers in the stratum corneum was identified as an important parameter and the effect of changing numbers of cell layers was simulated. The simulation could then be used as a hypothesis and tested using skin with varying layers of cells in the stratum corneum in flow-through cell experiments.

## CONCLUSIONS

PBPK modeling is an evolving frontier in toxicokinetic modeling. As our understanding of the systems and processes involved in toxicokinetics improve and expand, so does our ability to use newly gained knowledge in models. PBPK models allow for the adaptability needed to simulate varied physiological processes and system conditions. PBPK models are therefore likely to assume an ever more important role in our efforts to understand and predict the consequences of exposure to toxicants, and its application in veterinary toxicology can be expected to expand.

# Factors affecting chemical toxicity

Carlo Nebbia

## INTRODUCTION

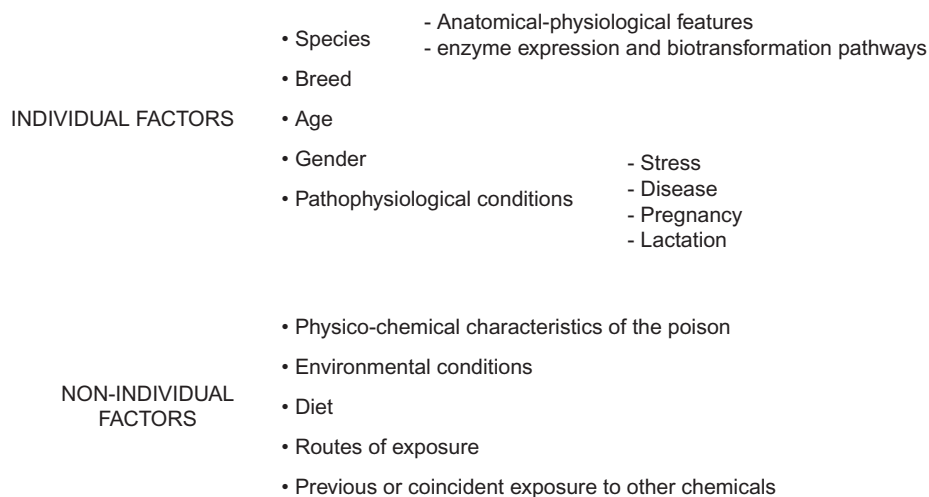

It has long been known that the sensitivity to the adverse effects of xenobiotics is not the same for all species. For example, unlike most mammals, rabbits may ingest large amounts of belladonna (*Atropa belladonna*), an extremely toxic herbaceous plant belonging to the Solanaceae family, without showing significant adverse effects due to the expression of an esterase able to hydrolyze the tropane alkaloid atropine. As a further example, anatomical-physiological features like the substantial inability of vomiting displayed by horses and rats make such species more vulnerable to a wide array of poisons in that, contrary to the other monogastric species, they lack a significant mean of limiting their absorption. On the other hand, the hydrolytic and reductive reactions mainly carried out by the ruminant biota may have opposite effects (i.e., increase vs. decrease of toxicity) according to the nature of chemicals ruminants may be exposed to.

It is also well assessed that the exposure of a population to a given amount of a toxicant may not affect each individual to a similar extent owing to the occurrence of several factors capable of modulating the overall toxic response. Breed may be of importance. Certain shepherd dogs like collies display a high sensitivity to a number of drugs (e.g., avermectins, loperamide and many others) because a significant percentage of such animals do not adequately express certain efflux proteins limiting the drug passage across the blood-brain barrier. Age is also an important determinant of chemical toxicity for most compounds, that is toxicity is generally higher in younger individuals for a number of reasons including, among others, a limited ability in the biotransformation and excretion of xenobiotics. Very little is known as to the

role played by gender and pathophysiological events like starvation, pregnancy and infectious diseases in modulating the response to poisons in veterinary species; stress is generally reported to worsen the clinical picture of several toxic syndromes and even to act as the starter event in the onset of copper toxicosis in sheep.

A number of non-individual conditions, i.e., of environmental origin as well as pertaining to or mediated by the xenobiotic itself, may also influence the response to foreign compounds. As regards the environmental factors, diet composition and notably dietary imbalances may be important determinants, as in the case of sulfur amino acids and antioxidants (e.g., selenium, vitamin E, carotenoids) for a large array of pro-oxidant drugs and toxicants like iron, copper, paraquat or acetaminophen. Even cold or warm atmospheric temperatures may play a role in exacerbating the toxic effects of certain chemicals. For a given poison, toxicity may also vary according to the particle size and the route of exposure. In some instances, certain pesticides, especially some organophosphorus derivatives, may spontaneously give rise to isomers of much higher toxicity (i.e., isomalathion) when stored in organic solvents or water. In addition to the above factors, the previous exposure to a number of chemicals known to respectively decrease (e.g., cimetidine, azole fungicides) or increase (e.g., phenobarbitone, organochlorines) the biotransformation capacity of a living organism may significantly alter the response toward poisons according to the toxicological properties of their metabolites. A telling example is the lower sensitivity to warfarin and other anticoagulant rodenticides of dogs subjected to phenobarbitone treatment for the prophylactic or therapeutic control of convulsive seizures of epilepsy.

Finally, a number of kinetics or dynamics interactions are described in which the concurrent administration of

**FIGURE 4.1** General scheme of the individual and non-individual factors affecting chemical toxicity.

one or more active principles, generally for therapeutic purposes, may displace a drug or a toxicant from its binding to plasma proteins, receptors or from the active site of enzymes involved in its biotransformation, leading to an abrupt increase in the concentration of the displaced compound with often severe and sometimes fatal consequences. The purpose of this chapter is to illustrate the main individual and non-individual factors capable of modulating chemical toxicity in veterinary species. A list of such factors is provided in [Figure 4.1](#).

## INDIVIDUAL FACTORS

### Species

#### *Anatomical and physiological features*

Vomiting is an important physiological function which may be of vital importance in limiting the bioavailability of an ingested toxicant, as often occurs in dogs and cats. In the horse, however, the marked tone at the cardiac sphincter makes vomiting a remarkably seldom event, which often occurs with gastric rupture ([Smith and Magdesian, 2009](#)). The incapability of vomiting displayed by rats has been taken into account to design targeted rodenticides like red squill, which is characterized by emetic properties notably increasing its safety for most domestic species ([Barnett et al., 1949](#)).

The effects of several poisons may vary to a considerable extent in polygastric vs. monogastric species. First of all, the considerable volume of ruminal fluid (100 to 225 L in cattle and 10 to 25 L in sheep and goats) leads to a dilution of toxic principles decreasing their absorption rates. Second, and most importantly, ruminal microorganisms carry out a number of biotransformation reactions, mainly

hydrolytic and reductive in nature, that are responsible for the bioactivation or detoxification of poisonous substances. Common examples for the first event are the hydrolysis of plant cyanogenic glycosides (e.g., dhurrin, amygdalin, etc.) leading to the release of cyanides ([Vetter, 2000](#)) or the reduction of nitrates to nitrites, which are largely implicated in nitrate toxicosis due to their vasodilating and methemoglobin-forming properties lacking in the parent compound ([Bruning-Fann and Kaneene, 1993](#)). On the contrary, both rumen protozoa and bacteria may detoxify many mycotoxins including ochratoxin A, which is hydrolyzed into the non-toxic ochratoxin  $\alpha$  and phenylalanine, and trichothecenes (T2-toxin, diacetoxyscirpenol and deoxynivalenol), mainly via a reductive de-epoxidation and hydrolytic deacetylation giving rise to much less toxic metabolites ([Swanson et al., 1987](#); [Yiannikouris and Jouany, 2002](#)). In addition, a bacterial lactonohydrolase is thought to convert the fusariotoxin zearalenone into the non-estrogenic product 1-(3,5-dihydroxy-phenyl)-10-hydroxy-1-undeca-6-one ([Takahashi-Ando et al., 2002](#)). An overview of the ruminal fate of a number of poisonous chemicals and the outcome of the biotransformation pathway (activation vs. detoxification) is presented in [Table 4.1](#).

Renal clearance of chemicals is largely affected by tubular reabsorption, which takes place by passive diffusion and thus depends on both the concentration of the xenobiotic in tubular fluid and its degree of ionization. The latter, in turn, is determined by the pKa of the compound under consideration and the pH of the tubular fluid, which may be assumed to be that of urine and is therefore influenced by dietary habits. Acidic values (5.5 to 6.9) are related to diets rich in animal proteins characterizing carnivorous species but also suckling or milk-fed individuals (e.g., veal calves), whereas alkaline values (7.2 to 8.4) are found in herbivorous species ([Baggot, 2001](#)). Therefore, it is anticipated that weak organic acids (e.g., paracetamol and many other NSAIDs, ochratoxin A) will

TABLE 4.1 Influence of rumen on the toxicity of selected compounds

Compound	Type of reaction	Metabolite	Outcome
Cyanogenic glycosides	Hydrolysis	Cyanide ions	Bioactivation
Ochratoxin A	Hydrolysis	Ochratoxin $\alpha$	Detoxication
Aflatoxin B1	Reduction	Aflatoxicol	Detoxication
Zearalenone	Hydrolysis	1-(3,5-dihydroxy-phenyl)-10-hydroxy-1-undeca-6-one	Detoxication
T-2 toxin	Hydrolysis (deacetylation)	HT-2 toxin	Detoxication

Nitrophenols	Reduction	Aminophenols	Detoxication

§ Hydrolyzed metabolites of various structure according to the nature of the parent compound

be present mostly in their non-ionized forms and hence efficiently reabsorbed in the presence of acidic urines, and the same holds true for weak organic bases (e.g., alkaloids like strychnine, caffeine or theobromine, and quaternary ammonium compounds) in herbivore urines.

#### Enzyme expression and biotransformation pathways

It is believed that the expression of glucose 6-phosphate dehydrogenase (G6PDH), especially in the erythrocytes, is comparatively lower in sheep with respect to the other species (Maronpot, 1972). This enzyme plays a key role in NADPH supply thus influencing the glutathione (GSH) reductase-mediated regeneration of GSH. Such tripeptide is part of a very effective antioxidant system including selenium-dependent GSH-peroxidase and vitamin E that contrasts hemoglobin oxidation to methemoglobin as well as its denaturation to Heinz bodies. Accordingly, sheep are expected to be particularly susceptible to pro-oxidant chemicals like copper, nitrites and chlorates or to hemolytic principles of vegetable origin like S-methylcysteine sulfoxide. Compared to other species, feline hemoglobin is markedly liable to oxidative damage; this has been attributed to both the presence of eight -SH groups per molecule and the ready dissociation of hemoglobin from the tetramer to dimer form (Harvey and Kaneko, 1976).

The biotransformation of foreign compounds is mainly mediated by hepatic and extrahepatic enzyme systems, collectively known as xenobiotic metabolizing enzymes (XMEs), aimed at increasing the hydrosolubility of the resulting metabolite(s) which may be more easily excreted via the urinary or the biliary routes. Two phases are essentially recognized. During phase I, different polar groups ( $-\text{OH}$ ,  $-\text{NH}_2$ ,  $-\text{COOH}$ ) are introduced or unmasked in the molecule's backbone, which enable them to undergo the subsequent phase II; it is accomplished by several families of cytochrome P450

(CYP)-dependent monooxygenases, different reductases, and enzymes capable of performing hydrolytic reactions called esterases or amidases. Phase II is synthetic in nature, in that a number of endogenous molecules such as acetate, sulfate, glycine, GSH or glucuronic acid are conjugated by their corresponding transferases to the parent molecules and/or to their phase I metabolites. While the conjugated metabolites are invariably of negligible toxicity, phase I metabolites may become more (re)active than the parent compound as a result of a bioactivation process, like for instance in the case of the CYP1A-mediated epoxidation of aflatoxin B1 (AFB1) to AFB1 epoxide or the CYP2B-dependent oxidative desulfuration of diazinon to diazoxon. Taking into account the influence of biotransformation processes on both the residence time and the activation/inactivation rate of a given chemical, it is therefore obvious that species-related overt differences in XME expression and functions may be considered as capital factors dictating the susceptibility to poisons (Nebbia, 2001). As regards phase I enzymes, however, only circumstantial evidence is provided by studies published so far concerning comparative CYP expression in domestic animals (Ioannides, 2006; Fink-Gremmels, 2008). For example, as documented by a very low oral  $\text{LD}_{50}$  (2–3 mg/kg body weight), the horse displays an unusual sensitivity toward monensin and other polyether ionophores antibiotics, which are widely used as coccidiostats and zootechnical additives in other livestock species. This is believed to reflect, among other factors, the relative lower ability of *Equidae*, as compared to many food producing species and the rat, to perform the CYP3A-mediated oxidation of such drugs yielding biologically inactive metabolites (Table 4.2), although further research is needed to confirm whether a comparatively lower CYP3A expression really occurs in the equine species (Nebbia *et al.*, 2001).

Likewise, in farm animals the magnitude of estrogenic effects arising from the exposure to the mycotoxin

TABLE 4.2 Sensitivity to ionophores of horses: relationship between the rate of the *in vitro* cytochrome P450-mediated oxidation of monensin, liver CYP3A content and the oral lethal dose of monensin in different animal species

Species	Oxidative monensin metabolism <sup>a</sup> (nmol · nmol cyt. P450 <sup>-1</sup> )	CYP3A content <sup>a</sup> (arbitrary units)	Monensin lethal dose <sup>b</sup> (mg · kg bw <sup>-1</sup> )
Horse	0.4	61	2–3
Rat	0.7	100	35
Swine	0.8	107	40–60
Cattle	1.5	123	60–80
Chicken	3	167	200

<sup>a</sup>Nebbia *et al.* (2001)

<sup>b</sup>Anadón and Martínez-Larrañaga (1991)

zearalenone correlates well with the extent of the generation of the  $\alpha$ -reduced metabolite  $\alpha$ -zearalenol over the  $\beta$ -stereoisomer cognate  $\beta$ -zearalenol, being maximal in the pig, intermediate in cattle and lowest in chickens. Whether such phenomenon reflects a species-related different expression of  $\alpha$ - or  $\beta$ -hydroxysteroid-dehydrogenases remains to be established (Fink-Gremmels and Malekinejad, 2007).

As to phase II reactions, it is known that the conjugation with GSH is the critical pathway in detoxifying aflatoxin B1 (AFB1)-epoxide (AFBO), a reactive metabolite accounting for both the AFB1-mediated cytotoxicity and the DNA-damaging effects. As detected by the measurement of the GSH-AFBO adducts in liver preparations, the remarkable susceptibility of the turkey to AFB1 has been related to the lack of apparent GSH-conjugation of AFBO, despite the presence of proteins cross-reacting with antibodies to GSH *S*-transferases isoforms (Yc and Yc<sub>2</sub>) performing such reaction in the rat (Klein *et al.*, 2002). Relevant qualitative species-related differences in phase II enzymes are indeed long recognized and some of these have been recently characterized at gene level. Compared to most mammalian species, cats are known to be more sensitive to phenol-containing compounds, including aniline derivatives such as acetaminophen (Court, 2001), many other NSAIDs, pyrethroids and a number of organophosphorus and carbamate derivatives. This feature, also shared by other *Felidae* and the domestic ferret (Court, 2001), has been linked to a structural defect of a gene encoding for the UGT (uridine diphosphoglucuronyltransferase) 1A6 enzyme giving rise to a non-functional protein (Court and Greenblatt, 2000). Another example involves the N-acetylation of arylamine drugs (e.g., *p*-aminophenol, sulfonamides), an important detoxification pathway catalyzed in most mammals by at least two N-acetyltransferases (NAT-1 and NAT-2). Poor N-acetylating capacity is found in cats (and in other *Felidae*) due to the lack of NAT-2 gene (Trepanier *et al.*, 1998), while the absence of both genes does not allow this reaction to occur at all in dogs and *Canidae* (Trepanier

*et al.*, 1997). An unusual sensitivity to the prolonged therapies with sulfonamides is commonly reported in dogs, and consists mainly of fever, arthropathy, blood dyscrasias (neutropenia, thrombocytopenia, or hemolytic anemia), cholestasis or hepatic necrosis, skin eruptions, uveitis, or keratoconjunctivitis sicca. The inability of dogs to carry out the N-acetylation of the arylamine derivatives causes the sulfonamides to be oxidized by CYPs and even by myeloperoxidases to hydroxylamines, which in turn may be bioactivated to reactive nitroso metabolites responsible for both cytotoxicity and hapten formation (Lavergne and Trepanier, 2007). More recently, the deficient N-acetylating capacity displayed by domestic carnivores has been implicated in the hematotoxicity characterizing the acetaminophen exposure, in that the *p*-aminophenol resulting from the carboxylesterase-mediated hydrolysis of the drug can no longer be acetylated back to the parent molecule and is therefore free to oxidize hemoglobin to methemoglobin in erythrocytes from exposed cats and dogs (McConkey *et al.*, 2009).

## Breed

The influence of breed in affecting the susceptibility to a number of drugs and toxicants has been identified for many years in domestic animals. For instance, Brahman cattle have been reported to be more sensitive to some organophosphates compared to other European breeds for still unknown reasons (Randell and Bradley, 1980). As a further example, the very low percent body fat characterizing greyhound dogs is likely to result in lower than expected volume of distribution and hence in higher serum drug concentrations as compared to that seen in breeds with higher percent body fat. This feature put the greyhounds and all “thin” dog breeds at higher risk for developing toxicity following the exposure to highly lipophilic compounds such as organochlorine or organophosphorus pesticides, and possibly many others (Fleischer *et al.*, 2008). In recent years, the rapid advancement of molecular techniques has allowed us to conclude that most of the observed population-based differences in sensitivity to drugs and toxicants is genetically determined and is almost invariably related to variation in XMEs and other proteins involved in drug kinetics (Mealey, 2006). Polymorphisms are defined as genetic variations occurring at a frequency of at least 1% in a given population. There is scant information in veterinary species about genetic polymorphisms relevant to the purposes of this chapter and most of the published literature is concerned with the canine species (Fleischer *et al.*, 2008). For example, both CYP2B liver expression and the related *in vitro* ability to oxidize the anesthetic compound propofol to its pharmacologically inactive metabolite 4-hydroxypropofol were remarkably lower in greyhounds

TABLE 4.3 Selected P-glycoprotein substrates

Class	Compounds	Class	Compounds
<i>Anticancer agents</i>	Doxorubicin	<i>Opioids</i>	Loperamide

\*Also CYP3A substrates

compared to beagle dogs. Taking also into account the consequences of the poor ability to store lipophilic compounds in fat depots mentioned above, these findings indicate that in greyhounds an adjustment of the propofol dosing regimen is required to avoid delayed recovery and other untoward effects (Hay Kraus *et al.*, 2000). While the specific genetic alteration responsible for the low CYP2B expression in such dog breeds is yet unknown, a true genetic polymorphism has been demonstrated for the gene encoding for thiopurine S-methyltransferase (TPMT), a phase II enzyme carrying out the detoxification of thiopurine drugs (e.g., azathioprine), which are widely used in humans and in companion animals to treat neoplasia and as immunosuppressants. A wide range of TPMT red blood cells activity was found in different breeds of dogs, with a nine-fold variation in median values between the giant schnauzer (lowest activities) and the Alaskan malamute (highest activities) (Kidd *et al.*, 2004). An almost six-fold variation in TPMT red blood cells activity was detected in 104 cats of unspecified breed, which was largely attributable to a TPMT gene polymorphism (Salavaggione *et al.*, 2004); the limited extent of thiopurine drugs inactivation occurring in low TPMT individuals results in life-threatening toxicity, most often myelosuppression (Rodriguez *et al.*, 2004).

Other well-defined genetic polymorphisms involving P-glycoproteins (P-gps) have been documented in dogs and are under investigation in other veterinary species like sheep, cattle and chickens (Mealey, 2006; Martinez *et al.*, 2008). P-gps are ATP-dependent pumps encoded by the MDR-1 (now ABCB1) gene; they belong to the

family of drug transporters and are expressed in a variety of tissues, i.e., the enteric epithelium, the brain capillary endothelial cells, the bile canaliculi, the renal tubular epithelial cells, the placenta, the ovary and the testes, where they catch selected xenobiotics (defined as “substrates”) and either extrude them out of the body (i.e., into the bile, the urine or the intestinal lumen) or prevent them from accessing certain vital sites (Gombar *et al.*, 2004). A list of such substrates is provided in Table 4.3.

In so doing, they play a key role together with XMEs in governing the absorption, the distribution and the excretion of xenobiotics, and a unique role in protecting the brain (blood–brain barrier), the genital organs and the fetus. An intriguing characteristic of such carriers is that a number of their substrates are also CYP3A substrates (Martinez *et al.*, 2008). The MDR-1 polymorphism in dogs is common in herding breeds (collies, old English sheepdogs, Australian shepherds, English shepherds, German shepherds, border collies, long-haired whippets, silken windhounds) and is based on a four base-pair deletion mutation causing a shift in the reading frame generating, in turn, a number of premature stop codons; in addition to the wild-type MDR1 (+/+), dogs may be homozygous, i.e., MDR1(–/–), or heterozygous, i.e., MDR1(+/–) for the mutation (Mealey *et al.*, 2001). A very high allelic frequency of MDR1 mutation has been detected in dogs, being as high as 55% in collies, 42% in long-haired whippets, and about 20% in Australian shepherds (Mealey, 2006). A moderate to sharp increase in both the overall bioavailability and residence time of P-gp substrates along with a wide array of adverse effects are therefore expected

in MDR(+/-) and, to a higher extent, in MDR(-/-) dogs, respectively. In such animals, macrocyclic lactones widely used as antiparasitic agents, such as ivermectin, moxidectin, milbemycin, and selamectin, are no longer, or only to a limited extent, prevented from crossing the blood-brain barrier and cause neurotoxicity (hypersalivation, mydriasis, ataxia, muscle tremors, depression and coma) following the exposure to therapeutic doses. A long-lasting central nervous system depression has been described in MDR(-/-) dogs treated with either the phenothiazine derivative acepromazine or the morphine derivative butorphanol (Mealey, 2006) and a similar syndrome has been observed in MDR1-mutant dogs orally administered with loperamide, a synthetic opioid used to control intestinal motility (Sartor *et al.*, 2004); all such drugs are characterized by a wide safety margin in wild-type individuals, in which they fail to enter the brain tissue. On the other hand, myelosuppression and gastroenteric disturbances have been reported in dogs homozygous for MDR-1 mutation subjected to anticancer therapy with doxorubicin or vincristine, and such severe side effects have been linked to a reduced rate of drug renal and/or biliary excretion (Mealey, 2006). Finally, a homozygous genomic deletion encompassing exon 2 of the COMMD1 gene playing a critical role in copper biliary excretion has been identified as the genetic cause of the canine copper toxicosis showing a high prevalence in Bedlington terriers (De Bie *et al.*, 2005) and closely resembling the Wilson disease described in humans.

## Age

It is generally accepted that sensitivity to the effects of drugs and other foreign chemicals is often greater in young and elderly individuals than in adult ones as the result of several factors including differences in the rate of absorption, binding to plasma proteins, distribution, biotransformation and excretion (Baggot, 2001). In newborn and lactating animals, the combined effects of a lower hepatic biotransformation rate and a less efficient renal excretion considerably decrease the rate of elimination of foreign chemicals. Although some species-related differences are reported to occur, it may be assumed that, in the majority of mammals aging about 12 weeks, both functions correspond to or approach those of adult individuals (Baggot, 2001; Hines, 2008). Another factor characterizing lactating individuals is the acidic urinary pH influencing the tubular reabsorption of weakly acidic xenobiotics (see above); in young ruminants, moreover, the lack of a functional rumen may also be of importance in affecting the overall outcome of the exposure to many toxicants. Accordingly, calves are reported to be particularly susceptible to a number of mycotoxins or to pesticides like organophosphates, carbamates, or pyrethroids,

which undergo a considerable breakdown in the ruminal environment. Theoretically, the reduced rate of CYP-mediated oxidations should lead to a parallel decrease in the generation of (re)active metabolites rendering young individuals less susceptible to toxicants requiring CYP bioactivation (e.g., thionophosphates, acetaminophen, aflatoxin B1, ipomeanol). However, it should be stressed that the final outcome of the exposure to any poison is dictated by the balance between bioactivating vs. detoxicating pathways, the latter being almost invariably performed by conjugating enzymes. Accordingly, the much higher sensitivity to AFB1 displayed by turkey poults with respect to adult ones is related to the remarkably lower expression of the GST isoenzyme Yc bearing a high affinity toward the CYP-mediated AFB1 epoxide (AFBO) (Klein *et al.*, 2002) and similar mechanisms are likely to occur in piglets (Clarkson, 1980) and chicks (Quezada *et al.*, 2000). With the likely exceptions of sheep (Kaddouri *et al.*, 1990) and goats (Eltom *et al.*, 1993), in which glucuronidating capacity would be already well expressed in the first weeks of life, the low expression of UGTs is considered one of the crucial determinants of the increased susceptibility of young animals to several poisons (Hines, 2008). As an example, while a low to moderate zearalenone contamination of feedstuffs often goes unnoticed in sows under field conditions, the poor glucuronidation rate of both zearalenone and its metabolites  $\alpha$ -zearalenol and  $\beta$ -zearalenol, which are known to cross both the placental and the mammary barriers, accounts for the marked susceptibility of newborn piglets to the estrogenic effects of such compounds (Dacasto *et al.*, 1995). The enteric absorption of certain toxicants may be enhanced in the early age. Possibly related to a high pinocytotic activity of the immature epithelium, an increased oral bioavailability has been demonstrated for a number of metals (lead, cadmium, iron, cobalt, zinc and mercury) in newborn or young individuals (Nordberg *et al.*, 2007), reaching up to 90% in the case of lead (Humphreys, 1991).

Finally, there is meager information concerning the effects of elderly on the sensitivity to poisons in domestic animals, and notably in food producing species because of the short duration of their life cycle. Impaired hepatic and renal xenobiotic clearance are described in elderly people, mainly due to reduced blood flow and glomerular filtration rate rather than to a significant decrease in the biotransformation capacity (Hilmer, 2008). Likewise, limited differences in the activity of hepatic phase I and phase II XME have been detected in adult vs. aged individuals in sheep (Kaddouri *et al.*, 1990) or dogs (Kawalek and El Said, 1990), while the expression and the activity of selected liver CYPs, hydrolytic and conjugative enzymes have been even reported to significantly increase in mares aged more than 12 years compared to those in the age range 1 to 2.5 years (Nebbia *et al.*, 2004).

## Pathophysiological conditions

### Stress

In sheep, the abrupt release of copper in the bloodstream starting the hemolytic crisis which characterizes the onset of copper toxicosis is triggered by stressful events like shearing or transhumance (Ortolani *et al.*, 2004); similarly, mild to moderate stressing conditions like loud noise, bright light and touch may provoke a fatal crisis in strychnine poisoned dogs (Talcott, 2006). Prolonged food and water deprivation may increase the toxicity of many drugs by reducing the rate of their elimination and lowering the concentration of certain antioxidants such as GSH (Bidlack *et al.*, 1986). An increase in the parent drug mean residence time and a reduced amount of both plasma glucuronide and sulfate derivatives were recorded in either food-withheld or water-deprived calves dosed with paracetamol, pointing to an inhibition of both UGTs and sulfotransferases (Janus *et al.*, 2003).

### Disease

It is generally accepted that diseased animals are less able to eliminate xenobiotics as the result of both a direct damage of organs and tissues involved in the biotransformation reactions and the alterations in protein binding, cofactor availability and renal clearance (Baggot, 2001). The complex events of the so-called “acute phase reaction” following the exposure to microbes or parasites include the release of several pro-inflammatory cytokines such as interleukin (IL)-1 $\beta$ , IL-6, and tumor necrosis factor (TNF) $\alpha$ . Such cytokines are responsible for both an overall reduction in the biotransformation capacity remarkably affecting CYP-dependent monooxygenases and UGTs in liver but also in extrahepatic tissues (Galtier and Alvinerie, 1996; Monshouwer and Witkamp, 2000), as well as of the inhibition of P-gps and of several other drug transporters (Petrovic *et al.*, 2007; Martinez *et al.*, 2008). Moreover, the synthesis of a number of acute phase proteins such as fibrinogen, haptoglobin and C-reactive protein, and the consequent alteration in the plasma protein profile, may result in an increase in the amount of unbound xenobiotics which are free to distribute in tissues and exert their pharmacological or toxicological action(s) (Mills *et al.*, 1997). Pre-existing kidney damage, as may commonly occur in aged carnivores, may also generally lower the rate of excretion of most chemicals and increase the toxicity of nephrotoxics such as ethylene glycole or melamine.

### Pregnancy

Little is known concerning the effects of pregnancy on chemical toxicity in veterinary species. The numerous physiological changes occurring in pregnant animals, especially concerning hormone secretion, increase in

plasma volume, decrease in plasma albumin concentration and increase in body fat (Martinez and Modric, 2010), are expected to considerably alter xenobiotic kinetics, but the underlying mechanisms still remain largely unknown. Plasma concentrations of steroid hormones, mainly estrogens and progesterone but also cortisol, are known to rise steadily during pregnancy and to activate some nuclear receptors (e.g., estrogen receptor  $\alpha$ , constitutive androstane receptor) resulting in a complex modulation of several XMEs. In pregnant women, a number of enzymes are known to be up-regulated (CYP2A6, 2D6, 2C9, 3A4 and UGT1A4), while others (CYP1A2 and CYP2C19) are reported to be depressed; consequently, the *in vivo* clearance of a number of drugs may be increased (e.g., nicotine, phenytoin, glyburide, etc.) or decreased (e.g., caffeine, theophylline) (Jeong, 2010). As marked differences across species are known, even between laboratory rodents, the overall effects of pregnancy on xenobiotic kinetics are difficult to predict in veterinary species, including dogs and cats (Rebuelto and Loza, 2010).

### Lactation

Lactation is reported to increase the clearance and the volume of distribution of many drugs (Martinez and Modric, 2010). Lactating animals may also excrete significant amounts of poisons through the mammary gland. In the case of highly lipophilic substances like polychlorodibenzodioxins/furans (PCDDs/PCDFs) and polychlorobiphenyls (PCBs), this implies on the one hand a significant reduction of the dam body burden through such additional way of excretion (Rychen *et al.*, 2008) but poses potentially toxic risks to the suckling offspring. In this respect, experimental studies conducted in goats and cattle have demonstrated that greater quantities of PCDDs, PCDFs or PCBs are transferred via suckling to neonates than through the placenta to fetuses (Lyche *et al.*, 2004; Hirako, 2008). Alterations of the plasma gonadotropins profile, decrease in plasma testosterone levels and increase in sperm DNA damage were recorded in goat kids exposed to PCB153 both during the second half of gestation and through lactation until weaning, which takes place about 40 days after parturition (Oskam *et al.*, 2005). According to Panter and James (1990), many plant toxins may be excreted in milk and cause toxicosis in suckling ruminants and foals. This is the case for tremetol and tremetone from white snakeroot (*Eupatorium rugosum*) or rayless goldenrod (*Haplopappus heterophyllus*) inducing the so-called “milk fever” characterized by severe muscle, myocardial and liver damage, or for the hepatotoxic pyrrolizidine alkaloids mainly found in the Boraginaceae (*Heliotropium* spp.), Leguminosae (*Crotalaria* spp.) and Compositae (*Senecio* spp.) families. Glucosinolates are glycosides found in many crucifers of genus *Brassica* that are important for animal nutrition,

such as rapes, kales, cabbages, turnips and others; upon hydrolysis, glucosinolates yield a number of derivatives including goitrin, thiocyanates and isothiocyanates, capable of depressing thyroid function. Reduced growth rate and lowered serum thyroxin levels were found at weaning in kids fed on milk from goats administered defatted meal of meadowfoam (*Limnanthes alba*), a glucosinolate-containing Limnaceae (White and Cheeke, 1983). There is also evidence that cyanides released from cyanogenic glycosides as well as their metabolites thiocyanates may also be transferred to milk and be responsible for a chronic syndrome in suckling goat kids associated with histological changes in brain, thyroid, liver and kidney (Soto-Blanco and Górniak, 2003). In some instances, according to the amount and/or the nature of toxic chemicals excreted through the mammary gland, the contaminated milk may be the cause of acute toxicosis. The documented excretion of zearalenone and its metabolites  $\alpha$ -zearalenol and  $\beta$ -zearalenol in porcine milk (Fink-Gremmels and Malekinejad, 2007) has been associated with the onset of a severe hyperestrogenic syndrome in suckling female piglets (Dacasto *et al.*, 1995). As a further example, cats may become acutely poisoned by metaldehyde by ingesting milk from an intoxicated cow (Gennaro Soffietti and Nebbia, 1984).

## NON-INDIVIDUAL FACTORS

### Physico-chemical characteristics of the poison

The physical state of the toxicant is of importance. Fine particles are more readily absorbed than coarse ones; in the case of poisons bearing irritating properties (e.g.,  $\alpha$ -naphthylthiourea, zinc phosphide), however, small size particles come into contact with a wider surface of the gastric mucosa and hence may more likely elicit protective vomiting.

When using commercial preparations of pesticides, it is always recommended to follow the datasheets and the instructions for safe use and disposal, avoiding the use of out-of-date products, solutions or emulsions. Such precaution is mandatory for certain organophosphorus insecticides for which storage activation is described with the subsequent spontaneous formation of highly toxic isomers; this phenomenon, which is increased by heat, is reported to continue when the pesticide is diluted and stored. Diazinon, a widely used phosphorothioate insecticide supplied as an emulsifiable dip concentrate for the fight against a wide array of ectoparasites in ruminants, has been involved in a toxic outbreak in which 81 of a group of 210 lambs died within 12 hours after being dipped with the contents of a partly used container of 15-year-old sheep dip. Analysis of dip samples revealed

the presence of a number of highly toxic spontaneous hydrolysis breakdown products of diazinon, including TEPP, sulfoTEPP and the oxon derivatives of diazinon and TEPP (Sharpe *et al.*, 2006). In addition, trichlorophon, which is sold as a wettable powder to control external parasites of cats and dogs, may be easily converted in alkaline solutions to dichlorvos, which is characterized by an eight-fold lower oral LD<sub>50</sub> in rats compared to the parent compound (Fonnum and Lock, 2000).

Solvents and other substances included in commercial preparations may also affect the overall toxicity of the active principle(s). Non-polar solvents may considerably increase the absorption rate of lipophilic poisons, especially when considering the exposure by the dermal route. Piperonyl butoxide (see below) is added to many carbamate- or pyrethroid-based formulations to lower the CYP-mediated detoxification of such compounds thus increasing their insecticidal potency. In other instances, molecules other than the active principle(s) are responsible for some (if not most) of the recorded adverse effects. This is the case of the herbicide Roundup®, a commercial formulation containing 12–50% glyphosate, an organophosphate displaying no anticholinesterase activity, and very low bioavailability and toxicity (oral LD<sub>50</sub> >3500 mg/kg body weight in both goats and rats). The toxic syndrome resulting from the ingestion of recently treated grass and vegetation, including signs of gastrointestinal irritation, swelling of lips and nervous depression, is largely attributable to polyoxyethylene amine, a surfactant used to enhance the penetration of the waxy surfaces of plants by the active ingredients, which has an oral LD<sub>50</sub> in rats of about one third that of glyphosate (Campbell and Chapman, 2000).

### Environmental conditions

High ambient temperatures are reported to enhance the toxicity of chlorophenols and nitrophenols that cause an increased production of heat by uncoupling mitochondrial oxidative phosphorylation (Fikes *et al.*, 1989). Conversely, cold temperatures are predisposing factors for  $\alpha$ -chloralose, a rodenticide/avicide formerly used as an anesthetic agent, which may induce a life-threatening hypothermia especially in poisoned cats by acting on hypothalamic thermo-receptors (Segev *et al.*, 2006).

### Diet

Poor or unbalanced diets, particularly when deficient in certain trace elements or in antioxidants, may significantly increase the dangerousness of a number of toxicants. Diets low in sulfur and molybdenum are reported to increase the susceptibility of sheep to copper, due to

the ability of such elements to promote the formation of relatively insoluble complexes limiting copper bioavailability (Nederbragt *et al.*, 1984). Likewise, copper-deficient ruminants are more prone to develop molybdenosis, a syndrome characterized by scouring, weight loss, hair depigmentation, reproductive impairment and even death (Raisbeck *et al.*, 2006). A primary vitamin K deficiency seldom occurs, but prolonged oral or parenteral therapies with certain antibacterial drugs may suppress the enteric flora resulting in a lack of vitamin K synthesis predisposing dogs and other non-target species to anticoagulant rodenticides toxicity (Prater, 2006).

Diets should also ensure a proper supply of sulfur amino acids, which participate in the control of oxidative status due to their involvement in the synthesis of GSH in tissues and erythrocytes (Tesseraud *et al.*, 2009), and of other components of the antioxidant systems including, among others, selenium, as cofactor of GSH-peroxidase (Se-GSHPx), vitamin E and ascorbic acid. Dietary deficiencies in one or more antioxidants are important risk factors for toxicants being biotransformed to reactive metabolite(s) or generating reactive oxygen species. Low GSH levels have been implied as a major condition in enhancing the liver toxicity of acetaminophen in cats and dogs, due to the consequent reduced ability to form nontoxic GSH-adducts with the CYP2E1-mediated reactive imino-derivative (NAPQI, i.e., N-acetyl-*p*-benzoquinoneimine) of the analgesic drug (Savides *et al.*, 1985). In this respect, the oral administration of bioflavonoid antioxidants to cats elicited a beneficial effect on their ability to resist acetaminophen-mediated oxidative injury to erythrocytes (Allison *et al.*, 2000). Iron oral or parenteral supplementation to piglets represents a common practice in piggeries to prevent neonatal anemia. Piglets from sows fed diets marginal in vitamin E or rich in polyunsaturated fatty acids, which may cause a secondary vitamin E deficiency due to the relative ease of undergoing peroxidation, are much more susceptible to develop lethal toxicoses with routine iron treatments than piglets nursing dams fed a vitamin E-supplemented diet (Lipinski *et al.*, 2010). On the other hand, selenium but not vitamin E supplementation to chicks was able to reduce the lethality of paraquat, a dipyrldyl-herbicide whose toxicity is based on redox cycling and intracellular oxidative stress generation (Combs and Peterson, 1983).

## Routes of exposure

For most xenobiotics, parenteral routes of exposure entail a more prompt and complete bioavailability than the oral one and therefore often result in a lower LD<sub>50</sub>. In addition, orally ingested poisons may undergo a first pass metabolism that in certain cases may lead to an almost complete detoxification. As an example,

pyrethrum-based insecticides are practically nontoxic in mammalian species, in which they are extensively hydrolyzed in the gut, but not in fish, where a significant amount of the molecule may enter the body through the gills. As a consequence, while the oral LD<sub>50</sub> of pyrethrin in the rat amounts to 1500 mg/kg body weight, it is as low as 5.2 µg/L in the trout (*Onchorhynchus mykiss*) (Anadón *et al.*, (2009)).

## Previous or coincident exposure to other chemicals (drug–drug interactions)

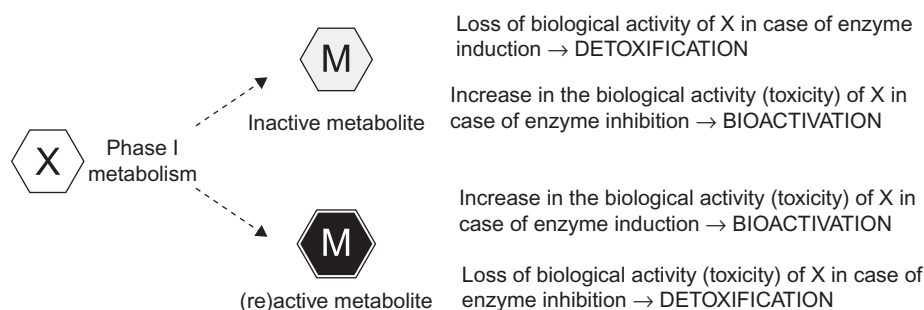

A variety of chemicals (drugs, plant toxins, pesticides, environmental pollutants) animals may be exposed to are capable of increasing (enzyme inducers) or decreasing (enzyme inhibitors) the expression and the activity of hepatic and extrahepatic phase I and phase II enzyme systems participating in the biotransformation reactions hence modulating the toxicity of several xenobiotics. A detailed description of the nature of inducers or inhibitors and the mechanisms by which they affect XMEs is beyond the scope of this chapter (for a review see Lin and Lu, 1998; Handschin and Meyer, 2003). As regards enzyme induction, suffice it to say that generally this phenomenon takes place slowly as it requires a prolonged exposure to the inducing molecule(s). Phase I enzymes and most notably CYPs are more inducible than conjugating enzymes, with the remarkable exception of UGTs and GSTs. More to the point, while inducers like phenobarbitone (PB), organochlorine insecticides or PCDDs are able to affect both phase I and inducible phase II enzymes, others are much more selective, as is the case of rifampicin or certain macrolides known to induce CYP3A, or of short chain alcohols which are reported to induce CYP2E1. Conversely, chemical-mediated inhibition may occur even after a single exposure and generally involves a single enzyme, which is almost invariably a CYP. The most common forms of inhibition are the competition between two or more chemicals for the same CYP and the formation of complexes between certain molecules (e.g., macrolides, tiamulin, piperonyl butoxide, ketoconazole and other azole fungicides) and a given CYP (in most cases CYP3A). A list of the main CYPs involved in xenobiotic biotransformations, with the most important inducers and inhibitors, is depicted in Table 4.4. For a given toxicant, the modulation of the biotransformation capacity mentioned above may have different clinically relevant outcomes according to the nature of the toxicant under consideration and of its resulting metabolite(s) (Figure 4.2).

In the case of enzyme induction, a decrease of the overall toxicity is expected if the parent compound itself is responsible for the toxic action(s), while the opposite holds true whether one or more (re)active metabolites arising from biotransformation reactions mediate(s)

**TABLE 4.4** List of the main substrates, inducers and inhibitors of CYPs involved in xenobiotic biotransformation in veterinary species

CYP	Substrates	Inducers	Inhibitors
1A	Large planar molecules (e.g., benzopyrene, benzanthracene, polychlorodibenzodioxins, co-planar polychlorobiphenyls, aflatoxin B1), caffeine, theophylline	Polychlorodibenzodioxins, polycyclic aromatic hydrocarbons	Furafylline, $\alpha$ -naphthophlavone, enrofloxacin (?)
2B	Barbiturates, anesthetics (e.g., propofol, ketamine, midazolam) phosphorothioates (e.g., diazinon)	Phenobarbitone	Chloramphenicol, medetomidine, atipamezole
2C	4-Hydroxycoumarin derivatives (e.g., warfarin), tolbutamide, NSAIDs (e.g., naproxen, ibuprofen, diclofenac), diazepam	Phenobarbitone	Sulphaphenazole
2D	Bufuralol, debrisoquine, celecoxib	–	Quinine, quinidine
2E	Small molecules (e.g., alcohols), acetaminophen, acetylsalicylates, anesthetics (e.g., methoxyflurane)	Ethanol	Disulfiram
3A	Most drugs, sexual steroids	Dexamethasone, rifampicin	Tiamulin, erythromycin, triacetyloleandomycin, ketoconazole

Data derived from Lin and Lu (1998); Nebbia (2001); Ioannides (2006); Fink-Gremmels (2008)

**FIGURE 4.2** Consequences of the modulation of the activity of biotransformation enzymes on the toxicity of a given xenobiotic according to the activity of its metabolite(s).

the toxic damage. Although enzyme induction has the potential to modulate the toxicity of a large number of xenobiotics, relatively few examples concerning veterinary species are quoted in the literature. In clinical practice PB is one of the most commonly employed drugs to prevent the onset of seizures in dogs affected by idiopathic epilepsy. One of the most known side effects of PB therapy is the induction of a number of phase I and phase II XMEs, particularly of CYP2B11, CYP2C21 and CYP3A12, which may last up to 4 weeks after the barbiturate is discontinued (Fukunaga *et al.*, 2009). It is anticipated that PB-induced dogs (and probably individuals from other species) are less susceptible to warfarin and possibly other anticoagulant rodenticides (Fink-Gremmels, 2008), pyrethroids (Anadón *et al.*, 2009) and even strychnine (Hatch, 1982a) due to the relatively low toxicity of phase I and phase II metabolites. Little is known about the opposite situation, such as if a bioactivation reaction occurs. To fully acquire

their anticholinesterase activity, for example, insecticidal phosphorothioates (e.g., parathion, diazinon, bromophos, fenthion) require desulfuration to their corresponding oxons, which is believed to be primarily mediated by CYP2B (Buratti *et al.*, 2003), a CYP family reported to be induced by PB and organochlorines (Fink-Gremmels, 2008). Accordingly, the pre-treatment of calves with a single dose of 10mg/kg dieldrin or 10mg/kg PB per day for 21 days increased the toxicity of diazinon as reflected by both the development of more severe clinical signs and a greater depression in whole blood cholinesterase activity with respect to non-induced calves. Interestingly, since the pre-treatment brought about a concurrent increase in the hepatic microsomal activity of both CYP-dependent monooxygenases and of carboxylesterases, it may be concluded that the effects of PB or dieldrin induction were more prominent on the bioactivating (i.e., oxidative) pathway rather than on the detoxifying (i.e., hydrolytic) one

(Abdelsalam and Ford, 1986). Other examples related to the effects of XME inducers on xenobiotic toxicity may be found elsewhere (Nebbia, 2001; Graham and Lake, 2008).

Opposite to enzyme induction, enzyme inhibition is expected to entail beneficial effects in poisonings from toxicants that necessitate a metabolic activation; in certain cases, inhibitors may be used for therapeutic purposes. Cimetidine is recommended to treat acetaminophen toxicosis in dogs and cats because of its inhibitory effects on CYP-mediated generation of the reactive metabolite NAPQI (Fooshee Grace, 2006), which is responsible for the severe liver injury occurring in poisoned animals. As a further example, dogs poisoned by the antifreeze ethylene glycol are treated with 4-methylpyrazole owing to its inhibitory properties toward alcohol dehydrogenase, a cytosolic enzyme catalyzing the oxidation of the parent compound to several metabolites, including glycoaldehyde, glycolic and glyoxylic acids, and oxalic acid, which play a key role in the pathogenesis of ethylene glycol intoxication (Connally *et al.*, 2010). By contrast, enzyme inhibition may enhance the toxic potency of chemicals acting *per se*, i.e., not requiring a metabolic activation, and provides a rationale for explaining many drug–drug interactions also in veterinary species (Fink-Gremmels, 2008). As mentioned before, the most common event is the concurrent administration of (or exposure to) at least two compounds being metabolized by the same CYP(s); in such cases the one showing the greater affinity toward the enzyme involved in its metabolism or being present at higher concentrations may displace the other(s) which remain unmetabolized. Monensin and other ionophores, used worldwide as coccidiostats and zootechnical additives in food producing species, are mainly biotransformed by CYP3A (Nebbia *et al.*, 1999, 2001), the CYP family mostly involved in the metabolism of medicinal substances, yielding oxidized metabolites almost devoid of biological activity (Donoho, 1984). A concomitant administration with drugs displaying a much greater affinity toward CYP3A, such as tiamulin (Nebbia *et al.*, 1999) or macrolides, will cause the unmetabolized ionophores to build up and elicit a severe toxic syndrome in pigs, cattle and avian species involving myocardium, skeletal muscles and the central nervous system (Langston *et al.*, 1985; Szucs *et al.*, 2004). It should not be overlooked that, under conditions of repeated exposure, a number of macrolides (e.g., erythromycin, triacetyloleandomycin, spiramycin) and tiamulin are characterized by a further inhibition mechanism. This involves a CYP3A-mediated N-dealkylation followed by a further oxidation to a nitroso group that binds tightly to the ferrous heme of CYP to form both *in vitro* and *in vivo* a catalytically inactive stable complex without destroying the hemoprotein but slowing down considerably its turnover. Such mechanism has been demonstrated under *in vitro* conditions

in ruminants (Zweers-Zeilmaier *et al.*, 1999) and either under *in vitro* (Carletti *et al.*, 2003) or *in vivo* conditions in rabbits (Cantiello *et al.*, 2003).

The previous exposure to drugs and chemicals may also modulate the expression of P-gps and other drug transporters in veterinary species (Martinez *et al.*, 2008), but relatively few examples of practical relevance are quoted in the open literature. Ketoconazole, a broad spectrum orally active antifungal agent extensively used in veterinary medicine, is reported to inhibit both CYP3A and the P-gps in a variety of animal species including humans (Lin, 2007). The co-administration of ketoconazole and ivermectin to dogs induced both higher plasma concentrations and longer residence times of the latter, with the potential for neurotoxic adverse effects especially for animals displaying genetic polymorphisms of the MDR1 gene (Hugnet *et al.*, 2007).

Drug–drug interactions may also occur in the bloodstream. Anticoagulant rodenticides like warfarin, bromadiolone or brodifacoum are characterized by relatively long plasma half-lives due to a high degree of plasma protein binding. In many cases of anticoagulant rodenticide toxicity, the only clinical signs observed in dogs are rather non-specific (weakness, lethargy or anorexia); in addition, affected animals often display respiratory distress prompting therapeutic intervention. The concurrent administration of anti-inflammatory agents like acetylsalicylates and phenylbutazone or of sulfonamides may cause such drugs to displace the anticoagulant rodenticides from their albumin binding often leading to an abrupt worsening of the clinical picture (Murphy, 2002).

Finally, the co-administration of certain drugs may also modulate the toxicity of several poisons by acting at the receptor level. For instance, drugs that have neuromuscular blocking properties which are elicited through their action on nicotinic receptors (e.g., d-tubocurarine or succinylcholine) may enhance the toxicity of organophosphates or carbamates, while the reverse holds true in the case of the exposure to parasympatholytic agents like atropine, which is widely used as an antagonist in clinical practice (Hatch, 1982b).

## CONCLUSION

The exposure to poisons may elicit different outcomes according to a number of individual and non-individual factors. In most cases the variation in the toxic response is based on the different expression of enzymes or proteins involved in the kinetics of poisons, which may vary according to diet, species, breed and physiopathological factors, or the previous or concomitant exposure to several foreign compounds. While until recently such events could hardly

be explained, currently the unprecedented development of molecular techniques has made it possible to gain insight into many of the mechanisms underlying most of the differences in the response to foreign compounds.

# Toxicological testing: *in vivo* and *in vitro* models

Magda Sachana and Alan J. Hargreaves

## INTRODUCTION

The large number of new chemical entities in human and veterinary pharmaceutical industry has led to increased demand for safety screening to ensure successful drug development. Part of this screening process includes the determination of the toxic potential of these new compounds by applying internationally recognized *in vivo* or *in vitro* toxicological tests. The importance of toxicological testing is critical, as many pharmaceutical and agrochemical products have to be assessed for their safety, before they become available for general use. Furthermore, in some cases, basic research can produce data that eventually leads to the ban of certain chemicals because they were proved to be unsafe.

Animal studies and validated *in vitro* models are extensively used for screening of agents in order to identify and predict potential ill-effects to humans, domestic and farm animals. Although the detection of adverse health effects of xenobiotics is the main objective of toxicity testing, it can be complemented by more sophisticated biomolecular approaches aimed at the elucidation of the mechanisms of action of certain chemicals.

Another area of veterinary interest regarding toxicological testing is the evaluation of the safety of veterinary drugs for food animals, as well as the safety assessment of veterinary drug residues in human food of animal origin, in order to determine the doses that cause non-observed effect level (NOEL) and consequently to establish the acceptable daily intake (ADI) in human diet.

Toxicological testing laboratories now have to comply with strict official controls and inspections on animal use at any time that can be reinforced by relevant legislation. In most European countries, veterinarians play a pivotal role in toxicity testing and are required by law to be employed by designated establishments that undertake experiments on animals, including toxicological studies. More specifically, a named veterinary surgeon is responsible not only for the health and well-being of laboratory animals but also to advise on the selection of adequate *in vivo* models and ensure that priority is given to the use of alternative methods during the local ethical review process. Furthermore, the refinement of experimental techniques and husbandry approaches should be one of the priorities of a veterinary surgeon working in animal units, especially where regulated procedures take place, and distressed animals should be kept under very close supervision by a veterinarian. A similar approach is used in the U.S., where all institutes are also obliged to establish an Institutional Animal Care and Use Committee (IACUC), where the participation of a trained and experienced veterinary surgeon is essential to ensure that all aspects of the 3 “R”s (replacement, reduction and refinement) (Russell and Burch, 1959) have been followed before approving animal use for toxicological studies.

A veterinarian with specific professional or scientific interest in toxicology should be aware of the alternative methods in toxicity testing, advise on replacement and refinement of laboratory animals used in toxicological studies and safeguard animal welfare. The main aims of this chapter are to outline the major aspects of *in vivo*

and *in vitro* models in toxicity testing and to give a brief overview of endpoint determination. The principal focus will be to highlight some of the current *in vivo* and *in vitro* models available in toxicity testing and inform on new technologies and approaches used in this field.

## IN VIVO MODELS IN TOXICITY TESTING

### Introduction

With the continuous development of new chemicals and pharmaceutical products, laboratory animals have become important and well-established tools for the generation of *in vivo* toxicological data. Originally, *in vivo* experiments were aimed at the prediction of acute systemic toxicity usually in rodents. Currently, more sophisticated, targeted and multi-species approaches with well-defined endpoints and experimental protocols are applied to toxicological studies, especially for regulatory testing.

As the science of toxicology evolves, an increasing number of *in vitro* alternative tests have been validated or they are currently under development. However, in some cases, animal models in toxicity testing are irreplaceable, especially in the tests required by the regulatory authorities to protect human and animal health. Furthermore, there is public demand to know the toxicity risks posed in everyday life, which necessitates the use of animal models comparable to humans.

Although animals are relatively expensive experimental models compared to the alternative methods discussed later, there are several important reasons for their continued use. First, there is extensive information available on their normal biochemical and physiological properties. Second, the published data from the measurement of toxicological endpoints *in vivo*, using models of relevance to humans and domestic/farm animals, makes animal testing a valuable tool to predict toxicity.

The animals that are most commonly used in toxicological testing are rodents and rabbits (Table 5.1). Cats and dogs are used less frequently in toxicity testing (and mostly in preclinical toxicology or phase I pharmacological studies), whereas non-human primates are rarely used and mainly to study metabolism of toxic compounds. In this table are not included the studies conducted on companion animals to determine safety limits in products that are directly applied to cats or dogs (EPA, 1998a). The interested reader is referred to some more specialized books regarding animal toxicity testing (e.g., Arnold *et al.*, 1990; Gad, 2006) and some useful websites relevant to regulatory toxicological testing (e.g., <http://www.epa.gov/ocspp/pubs/>

[frs/publications/Test\\_Guidelines/series870.htm](frs/publications/Test_Guidelines/series870.htm) and <http://lysander.sourceoecd.org/vl=23534020/cl=14/nw=1/rpsv/cw/vhosts/oecdjournals/1607310x/v1n4/contp1-1.htm>).

### Animal welfare in toxicity testing

Animal welfare legislation is currently applicable in most countries to prevent misuse of animals in toxicological testing. In the U.S., the Animal Welfare Act as amended (7 USC, 2131-2156) provides guidelines and protection to animals used for scientific purposes including toxicity testing. In Europe, Directives 86/609/EC and 2003/65/EC have been recently replaced by Directive 2010/63/EU. The latter is based on the principle of the 3Rs and aims to upgrade the minimum standards for laboratory animals by introducing appropriate animal welfare indicators and better training and information for animal handlers. Furthermore, it is necessary that there is explicit and easy-to-follow documentation in each project license involving toxicological testing in animals, where the steps followed in the case of animal distress are described. Testing new chemical compounds on *in vivo* models can lead sometimes to pain, discomfort or animal distress. Animals exhibiting signs of suffering should be examined by a veterinarian or trained personnel and, if there is a good scientific reason to continue the study, administration of analgesics should be considered. Other options available are the euthanasia of the distressed animals and the decrease or the discontinuity of the test compound dose.

In general, there is a trend for improvements to enhance animal welfare, not only in animal housing (e.g., breeding, handling and feeding) but also in the same regulatory toxicity testing guidelines, by applying humane endpoints and decreasing the number of animals required (Combes *et al.*, 2004).

Handling laboratory animals and administering toxicological compounds is a stressful procedure for both the animals and the designated personnel. In recent years, there has been an attempt to apply the highest ethical standards not only by introducing an excellent environment and a social and complex housing but also by reducing and improving any invasive techniques used on laboratory animals.

Implanted biosensors are now available that permit the continuous telemetric monitoring of physiological and biochemical parameters in experimental animals, and have been proved useful in toxicological studies to minimize not only the artifacts due to animal handling and restraint but also to improve animal welfare. In addition, non-invasive and currently expensive methods such as magnetic resonance imaging (MRI) and nuclear magnetic resonance spectroscopy are available for the

visualization of pathological findings and determination of the distribution of a test chemical in laboratory animals, respectively, which further contribute to improved animal welfare.

### Routes of test compound administration

Toxicity testing in animal models is most useful if it imitates the human or domestic/farm animal route of exposure to chemical agents. Based on the medium of exposure in human and domestic animals, it is possible

to decide which is the administration route of choice in animal toxicological tests (Table 5.2). Depending on the route of administration, experimental evaluation may differ because of variation in the absorption, metabolism and elimination of a compound. Oral exposure can lead to absorption by the digestive system and metabolism by the liver, whereas, following inhalation, a toxic compound is more likely to be absorbed by the respiratory system. Metabolism of xenobiotics can also occur in placenta, in the test dam and fetus. This can lead to changes in the balance of parent compound and metabolites, complicating the picture even more in case of developmental toxicity tests.

This metabolism of administered chemical should be relevant to human or domestic animals and is critical for risk assessment exercises. The final toxic effect will depend on a balance between the level of toxic agent reaching the target tissue and its rate of elimination and/or bioinactivation by mixed function oxidases, serum hydrolases or binding to serum proteins. Furthermore, there are interspecies differences regarding the metabolism of xenobiotics (Nebbia, 2001). For example, cats are at high risk of developing hepatotoxicity especially after paracetamol administration. This is due to differences in

bioactivation of paracetamol, which occurs only in cats through *N*-hydroxylation with the help of cytochrome P450 2E1, during the oxidative reactions in phase I transformation (Nebbia, 2001). Ruminants are less susceptible to organophosphates (OPs) such as parathion than monogastrics, because the rumen microflora plays an important role by reducing the nitro group of OPs to an amino group (Nebbia, 2001).

The majority of toxicological studies commonly employ administration of the agent in animal feed or water or by stomach intubation (i.e., by gavage) in order to imitate a known or potential human or domestic animal exposure. The use of oral gavage is commonly used in administration of high doses of xenobiotics and in developmental toxicity tests, but is less practical in the case of long-duration studies. Inhalation is used when there is a need to duplicate industrial or environmental exposure to dusts, aerosols and fumes. In this case, nose, head or whole body exposure chambers are used, depending on the exposure time. For cutaneous administration, a toxic agent may be injected intradermally or simply applied topically on the skin or ears and sometimes covered with bandages. In case of experimental studies where the need for complete absorption of a tested compound is considered essential, parenteral routes of administration (intraperitoneal, intramuscular, intravenous and subcutaneous) are selected. However, the solubility and bioavailability of the tested agent can also influence the degree of absorption and how much of it is directly available in a laboratory animal.

Toxicokinetic and pharmacokinetic information on tested compounds and their comparison among laboratory animals and humans are also important to determine dosing parameters and improve the toxicological data obtained. The administered dose in toxicological studies should be decided taking into account many physicochemical parameters of chemical agents, biological differences between species, previously published data and after careful planning or preliminary experimentation.

## Reproductive toxicity tests

Reproductive toxicity testing is based on the measurement of reproductive functional and structural defects caused by toxic agents in both males and females. The toxicity endpoints most frequently studied in reproductive *in vivo* testing are summarized in Table 5.3. Rats and, to a lesser extent, mice are the species of choice in reproductive toxicological testing because they are considered inexpensive compared to bigger mammals (EPA, 2000; OECD, 2001a). On the other hand, small rodents need to be euthanized even for simple endpoints such as collection of sperm, whereas rabbits can be sampled

TABLE 5.3 Selective endpoints applied to laboratory animals during reproductive toxicity testing

regularly without being sacrificed, making them an alternative in reproductive toxicological tests (Foote and Carney, 2000). Some of the disadvantages of using rabbits are the higher cost due to greater amounts of chemical compounds administered and the increased cases of abortions because of the relatively high incidence of gastrointestinal dysfunction. For example, rabbits are poor models for veterinary residue testing and, more specifically, for antibiotics because these compounds have been found to cause diarrhea and consequently abortion (Barlow *et al.*, 2002).

Dogs have been occasionally used for reproductive toxicity testing, because the physiology of their reproductive system in both sexes has been extensively studied, contributing to significant background knowledge (FDA, 1982). However, the dog is not the model of choice in reproductive toxicity testing because it is a rather expensive animal model and the number of litters is not as high as in rodents. The main difficulty in running reproductive toxicological tests is the requirement for an estrous-synchronized population. Both the induction of ovulation by hormonal treatment and artificial insemination mainly in rabbits and dogs can overcome this problem and allow advanced planning for animal fertility studies.

Since exposure to chemicals can occur throughout life, a multi-generation study which extends over at least two generations, using a single type of laboratory rodent, is desirable in order to reveal reproductive toxicological data (OECD, 2001a; Barlow *et al.*, 2002; Garg *et al.*, 2011; Estevan *et al.*, 2011), although this approach requires large numbers of animals and it is time consuming.

## Developmental toxicity testing

Developmental toxicity testing is primarily used to determine hazard regarding the potential effects of

prenatal exposure on the developing fetus. These studies focus on functional and structural changes that can be observed throughout the development from zygote to neonate. The most important developmental phase is the organogenesis period that is always taken into account in developmental toxicity testing. Based on these studies, chemical compounds can be categorized as teratogenic and/or fetotoxic by recording structural malformations, developmental retardation and/or mortality, respectively. The vast majority of teratogenic chemical agents have been identified using rodent experimental models (EPA, 1998b, 2000; OECD, 2001b). However, the failure of rodents to detect teratogenic signal on some occasions and the similarities in placentation and pregnancy physiology between humans and rabbits led to the use of the rabbit as a second model for assessing the effects of toxic compounds on development (EPA, 1998b; Foote and Carney, 2000; OECD, 2001b). Furthermore, although non-human primates have been suggested as models for teratological testing (Buse *et al.*, 2003; Faqi, 2011), they have several limitations such as a long gestation period, only single or twin offspring, high rates of abortion and ethical constraints.

The detection rates for veterinary pharmaceutical agents demonstrated to be teratogenic/fetotoxic were found to be 55–79% using individual species (Hurtt *et al.*, 2003). However, when the rat and rabbit data were both considered, there was a significant increase in detection rate to almost 100%, suggesting that in the absence of teratogenicity in rat, a second species developmental test in lagomorpha is required to provide high standards of public protection (Hurtt *et al.*, 2003). The interested reader can retrieve some more information on reproductive and developmental toxicity testing by referring to a specialized book (Gupta, 2011).

### Cutaneous toxicity testing

The aim of *in vivo* assays for cutaneous toxicity is not only to assess potential acute local irritation but also to evaluate acute, subchronic and chronic systemic toxic effects. During cutaneous toxicity tests, animals are monitored for skin reactions/dermal effects, clinical, gross or microscopic pathological findings depending on the duration of a toxic compound administration and the observation period.

The albino rabbit has been until recently the animal model of choice because of the high permeability and sensitivity to toxic agents exhibited by its skin, which sometimes led to overprediction showing little relevance to human irritation (Auletta, 2004). Currently, albino rats and occasionally guinea pigs are considered preferable species to assess local irritation. Traditionally, guinea pigs and mice have been used also to perform

sensitization tests (EPA, 2003). On the other hand, long-term cutaneous toxicity studies usually require the use of a rodent (albino rat and mouse) as well as a non-rodent model. Minipigs have been proved to be a reliable non-rodent species because their skin demonstrates many physiological similarities with those of humans and pigs (Auletta, 2004). Other non-rodent models are dog and non-human primates, commonly used to test the metabolism of toxic agents and the safety of newly designed recombinant pharmaceutical products (Vail *et al.*, 1998; deBlois and Horlick, 2001).

### Genotoxicity testing

The aim of genotoxicity testing is to detect gene damage induced by the test compound, by measuring chromosome aberration and breakage, point mutation, and other DNA and chromosomal effects *in vivo*. The host-mediated assay is based on the inoculation of a microorganism into a rodent such as mouse, rat or hamster and subsequent assessment of the point mutations found in the microorganisms, after certain treatment of the rodents with the potential mutagen (Gabridge and Legator, 1969; Dhillon *et al.*, 1995; Loomis and Hayes, 1996). On the other hand, to identify chromosome breakage, male rodents are treated with the test compounds and, after mating with untreated females, fetal mortality and survival are recorded (OECD, 1984; EPA, 1998c).

The mouse spot test is capable of detecting somatic gene mutations and is based on *in utero* exposure to the tested chemical. This *in vivo* mutation test works by monitoring the appearance of colored spots in the coat of the animal that may appear due to altered or lost specific wild-type allele in a pigment precursor cell (EPA, 1998h).

A popular *in vivo* test to identify genetic risks is the rodent bone marrow micronucleus test, although it is not the most sensitive test and it does not improve predictivity of rodent genotoxicity when combined with *in vitro* tests (OECD, 1997a; Zeiger, 1998). However, this *in vivo* test is widely used because it is relatively easy to perform. Another *in vivo* test that has been validated and recommended by the Organisation for Economic Cooperation and Development (OECD, 1997b) is the rat liver unscheduled DNA synthesis (UDS) test. It is worth mentioning that none of the above approaches are suggested to be used individually to predict genotoxicity. Negative or positive results should always be confirmed first by *in vitro* or non-mammalian mutagenicity tests.

### Carcinogenicity tests

*In vivo* assays of carcinogenicity examine the possibility that a tested agent might cause tumors and other

chemically related effects in one or more animal species. Currently available is the rodent carcinogenicity test (OECD, 2009a). This test runs for up to 2 years and involves the use of three different concentrations, one administration route and both sexes. The results are based on clinical chemistry, gross and histopathological analysis of more than 40 tissues and organs in order to determine the site, the number and type of tumors (OECD, 2009a, b).

One serious disadvantage of using mice in carcinogenicity testing is their tendency to present high incidence of spontaneous liver or lung tumors in some strains, leading occasionally to inconclusive results (Gad, 1998). Furthermore, because of the long duration of carcinogenicity tests and therefore the old age of laboratory animals, it means that the natural occurrence of tumors increases, making it difficult to distinguish between a real treatment and a background carcinogenic effect. In addition, the most common mechanisms of tumor development in rodents may not be relevant to human carcinogenicity, posing limitations to any attempt to use *in vivo* data for carcinogen risk assessment.

Tumorigenic tests using dogs are limited because of the high cost and the long duration of the studies (up to 7 years). Furthermore, dogs demonstrate high susceptibility to aromatic amines and therefore care should be taken when using these animals for the evaluation of potential carcinogenic compounds of this category (Loomis and Hayes, 1996).

## Neurotoxicity

The neurotoxic potential of chemical compounds can be assessed by determining relevant effects on the autonomic or central nervous system (CNS), not only in adult but also in developing animals. Clinical signs including changes in behavior (e.g., movement, motor coordination or reflexes, paralysis, tremor, learning and memory), neurochemical (e.g., activity of enzymes associated with neuropathies, cell signaling pathways, synthesis, release and uptake of neurotransmitters), neurophysiological (e.g., electroencephalography, nerve conduction velocity) and neuroanatomical effects are commonly explored.

Rodents are the most frequently used animal models and there are a considerable number of available guidelines to examine the neurotoxicity of xenobiotics on them (OECD, 1997c; EPA, 1998d, e). However, an important issue related to the selection of animal model in neurotoxicity testing is the delayed onset of effects manifested by toxic agents. For example, in the case of assessment of the potential of OPs to produce delayed neuropathy induced by organophosphate (OPIDN), as rodents are not the most sensitive models, the use of the hen model is recommended (OECD, 1995a, b). The two protocols

used in the hen model involve either acute or repeated dosing for up to 28 days and determination of the enzymes acetylcholinesterase (AChE) and neuropathy target esterase (NTE), clinical observation and histopathology of the CNS (OECD, 1995a, b).

Furthermore, the need to address the specific risks of the developing nervous system has led to the application of more specific developmental neurotoxicity testing guidelines in rats (EPA, 1998f; OECD, 2007). Although rodents are the animal model of choice, the main problem using them in developmental studies is that the period of enhanced brain growth takes place during the first 10 days after birth, whereas in humans, dogs, guinea and mini pigs, this period is completed prenatally. In conclusion, for predicting developmental neurotoxicity risk in humans, the rat is the recognized model. However, dogs, guinea and mini pigs are also widely used to test pharmaceutical compounds that target children, due to the limitations of the rodent model (Kaufmann, 2003).

## Immunotoxicity

Immunotoxicity tests are designed to detect adverse effects of xenobiotics on the immune system including all the relevant cells, organs and mechanisms of immune response, whether or not there is a measurable disturbance in host resistance. Toxic substances can directly or indirectly cause immunotoxicity, either by inhibiting the enzymatic activity of esterases and serine hydrolases in the immune system or by chronic alteration in metabolism of organs in the immune and nervous system, respectively. Some of the approaches, tests and endpoints used to assess *in vivo* immunotoxicity are presented in Table 5.4 (EPA, 1998g; Barlow *et al.*, 2002; Galloway and Handy, 2003; OECD, 2008).

Laboratory rodents, especially mice, are used in toxicological tests because basic immunological studies were mainly conducted in this species. The immune elements and interactions in rodents and humans are very similar and if the toxicokinetic properties of tested chemicals are close, then the use of mice or rats is recommended (IPCS, 1996; EPA, 1998g).

Chlorpyrifos, an OP with distinctive toxic effects on neurodevelopment, was reported to affect intracellular signaling cascades involved in differentiation and proliferation of T lymphocytes (Blakely *et al.*, 1999) and has recently been implicated as an endocrine disrupting chemical, thus possibly affecting endocrine-mediated immunity. In most experimental studies, cholinergic doses of OPs were shown to reduce immune activity whereas non-cholinergic ones resulted in an increased response, although there is still research to be done to this direction (Pruett, 1992; Galloway and Handy, 2003; Sharma, 2006).

TABLE 5.4 Immunotoxicity endpoints, methods and approaches used for *in vivo* toxicity testing

Tests	Methods	Endpoints
Non-functional tests of immunotoxic response	Immunopathology	Lymphoid organ weight
	Routine hematology	Histopathology of lymphoid tissues, including bone marrow Immunocyte viability/differential count Immunoglobulin levels
Functional tests of immunotoxic response	Measurement of humoral immunity	Antibody response
	Measurement of non-specific immunity	Antibody plaque forming Neutrophil and monocyte numbers
	Measurement of cell mediated immunity	Phagocytic activity of macrophages Mitogen-induced cell proliferation
	Host resistance assays	Natural killer cell activity Mixed lymphocyte reaction Delayed hypersensitivity
		Mortality and organ histopathology due to bacterial, virus and parasitic infection

### Transgenic animals in toxicity testing

The recent advances in genetic engineering techniques led to the development of a number of transgenic *in vivo* models that can be used in toxicity testing, mainly in carcinogenicity and mutagenicity, as well as for the study of xenobiotic metabolism. These *in vivo* systems permit the study of toxicological effects of tested compounds on foreign genes of human or other origin that have been genetically transferred to produce transgenic animals, by transgenesis or targeted gene modification. From the point of view of toxicity testing, it is considered that such models will lead faster to results that are more representative of human response to xenobiotics. In addition, transgenic mice can bring significant animal welfare benefits, because they are able to reduce the group size needed in experiments and replace testing to other species, including non-human primates. Finally, these models are also excellent experimental systems and able to address and answer specific mechanistic questions in toxicology more efficiently (Valancius-Mangel and Doetschman, 1999). However, the use of "humanized" animal models in toxicological studies is an expensive process because it involves higher costs for their development and breeding. There is also concern that the human genome, once transferred to laboratory animals, may express the same proteins, but it does not guarantee that the protein will have similar function with that found in humans. In addition, there is limited background information on transgenic animals, making the interpretation of data in toxicological studies difficult (Valancius-Mangel and Doetschman, 1999).

The main transgenic genotoxicity systems used in toxicology to follow up *in vitro* genotoxicity positives are the Muta Mouse and Big Blue rat/mouse models,

in which the genome is "tagged" with the markers lacZ ( $\beta$ -galactosidase) and lacI, respectively (Gossen *et al.*, 1994; Winegar *et al.*, 1994; Wahnschaffe *et al.*, 2005a, b). Aflatoxin B1, a mycotoxin commonly found in human food and animal feed, has been tested in transgenic C57BL/6N mice and caused lacI mutation in animals' kidney and liver, proving the genotoxicity effect of the mycotoxin and demonstrating the usefulness of transgenic mice in toxicology because not only can this approach quantify mutant frequencies, it also identifies specific types of mutational events (Autrup *et al.*, 1996).

Several models are available to assess the carcinogenicity of a test compound: these include (1) inactivated tumor suppressor gene and DNA repair gene models such as p53<sup>+/−</sup> and XPA<sup>−/−</sup> knockout mice, and (2) oncogene activation models like the TgAC and the ras H2 transgenic mice (Valancius-Mangel and Doetschman, 1999).

Other important transgenic systems with toxicological application that have been designed to express/lack one or more of the proteins involved in metabolism of xenobiotics and their use has led to a better understanding of metabolic activation and transformation. Most of these transgenic models express human cytochrome P450 (CYP1A2, CYP1B1) or are knockout mice (CYP2E1/CYP1A2 null mice) (Valancius-Mangel and Doetschman, 1999).

### Limitations and implications of animal use in toxicological testing

The closer a test is to the phylogenetic species of concern, the more relevant the information obtained and the higher its predictivity. There are basic similarities

in biology and xenobiotic metabolism between humans and the different mammalian species used in toxicity testing, making *in vivo* testing the most reliable approach in chemical safety assessment (Knudsen, 1999). However, because of species and strain variability in uptake, metabolism and elimination of xenobiotics, no single type of animal is an ideal model for predicting human or domestic animal toxicity. Consequently, multiple *in vivo* models are usually required to determine toxicity of agents and to contribute to more precise risk assessment, which may have ethical implications.

Currently, there is a trend in using well-established inbred (immortal clones of genetically identical individuals) strains of rodents, in order to increase the sensitivity of animal experimentation in toxicological testing by maximizing the reproducibility of the results. While this approach can reduce animal numbers, the results may not be representative of a heterogeneous population; using a heterologous group of one species with low inbreeding may therefore be a more realistic approach reflecting the impact of a toxic compound on a broader spectrum of genes.

In the last three decades there has been an increased sensitivity to ethical issues involved in use of animals for toxicity testing. The tactics of mass demonstrations by animal protection and animal extremist groups has created an atmosphere where many institutions, organizations or companies and their employees are reluctant to support or carry out any animal testing, before making sure that an alternative test does not exist. In addition, there are economic arguments against the use of animals in toxicity testing. Approaches using animals are undoubtedly more time consuming and more costly to run, compared to *in vitro* models. There are certain standards that should be maintained from laboratories undertaking toxicity testing experiments, such as Good Laboratory Practices (GLP), not only from an animal welfare prospective but also from an experimental reproducibility approach, something that adds to the cost.

Furthermore, the quantity and quality of animal feed should also be considered because several studies demonstrated that the nutritional status can interfere with the reproducibility of the results obtained from animal models used in toxicity testing (Kacew, 2001). Other factors contributing to data quality are the health status of the animal stock (specific pathogen free, germfree or with ordinary microflora) and the laboratory experience in handling and caring for the stock. In conclusion, toxicological animal testing, although a valuable tool to predict human and domestic/farm animal toxicity of chemicals, is labor intensive, time and space consuming and raises important animal welfare concerns and uncertainties. For these reasons, there has been increasing interest in the development of *in vitro* alternatives that can help to reduce the use of animals in toxicity testing.

## IN VITRO MODELS OF TOXICITY TESTING

### Introduction

*In vitro* cellular models are relatively inexpensive and easy to maintain and manipulate compared to animal models. *In vitro* methods allow the study of direct cellular effects of toxins on specific cell or tissue types in a controlled environment.

However, the main disadvantage of *in vitro* systems over animal models is the lack of systemic effects such as an appropriate balance and supply of growth factors and a system of xenobiotic metabolism and elimination of toxins. The former can be at least partially addressed by adding appropriate growth factors and the latter can be addressed by the use of metabolic activation systems such as the introduction of nicotinamide adenine dinucleotide phosphate hydrogen (NADPH)-activated microsomes or a hepatic cell line in a cell culture well insert fitted with a filter (Figure 5.1). The toxin is introduced into the insert and a mixture of metabolized and non-metabolized toxin (but not the microsomes or the hepatic cells) diffuses through the filter into the growth medium containing the target cells. Another disadvantage is that many cellular systems lack the complexity of cell-cell interactions in tissue, although this can be addressed to varying degrees using co-culture systems or organ culture, which are discussed later.

### Types of cell culture system used in toxicity testing

Before discussing the assays used in the *in vitro* systems it would be useful to discuss the principles, strengths and weaknesses of the main types of *in vitro* system. All cell cultures need to be prepared and maintained under sterile conditions in order to reduce microbial contamination. Cells are maintained under defined conditions of humidity, pH and temperature. They are grown in a specific growth medium, which may have a number of supplements, such as antibiotics, glutamine, serum, etc., which are different for each cell line. Growth conditions should be optimized prior to experimental work. Excellent reviews on practical aspects of cell culture can be found in the following sources (Cohen and Wilkin, 1996; Shaw, 1996; Masters, 2000; Davis, 2002; Gardner *et al.*, 2004).

There are a number of types of cell culture available for *in vitro* testing that offer various degrees of complexity and relatedness to the *in vivo* situation. In order of increasing complexity and genetic similarity to the tissue of origin, these include permanent cell lines, primary cultures and organotypic cultures (Figure 5.2) (for

**FIGURE 5.1** Metabolic activation in cell culture systems.

Increasing complexity and similarity to <i>in vivo</i> systems	Culture type	Suitability/limitations
	Mitotic cell lines	Medium to high throughput studies of basal toxicity (e.g., membrane damage, viability, etc.) and cell proliferation. If immortalized, many cell lines are tumor-like. Limited cell–cell interactions and drug metabolism.
	Differentiating cell lines	Medium to high throughput screening and mechanistic studies of developmental toxicity and target cell specific toxicity. Often short-lived. Limited cell–cell interactions and drug metabolism.
	Primary cell cultures	Developmental or target cell-specific toxicity. Genetically more similar to target system but generally heterogeneous and short-lived. Can be used as co-culture systems (e.g., reaggregates) to simulate cell–cell interactions of target tissue but usually have limited drug metabolism.
	Organotypic/whole organ cultures	These are tissue slices or cultures organs that can maintain cell interactions and tissue function. Generally unsuitable for medium to high throughput analysis and may exhibit limited drug metabolism.

**FIGURE 5.2** Organization of a tiered system for *in vitro* toxicity testing.

reviews see [Noraberg, 2004](#); [Spielmann, 2005](#); [Sundstrom et al., 2005](#)).

Permanent cell lines are mitotic and can be finite, established or clonal in nature. They have the advantage that they are relatively easy and inexpensive to maintain compared to animals and they are amenable to cryopreservation under liquid nitrogen. However, if maintained through high numbers of divisions, there is

an increasing likelihood of genetic drift that might affect phenotypic properties of relevance to toxicity testing.

Finite cell lines are normally derived from primary cultures (see below) and can survive for 40–50 divisions before finally dying (e.g., fibroblasts). Established cell lines are effectively immortal, having been transformed with a virus, a mutagen or spontaneously. These are generally tumor like in nature; some widely used examples

include mouse 3T3 fibroblasts, HeLa cells and Chinese hamster ovary (CHO) cells. However, several cell lines can be induced to differentiate, making them potentially useful models of specific stages of development, for example the use of nerve growth factor or retinoic acid to induce a neuronal phenotype in cultures of rat PC12 pheochromocytoma and human SH-SY5Y neuroblastoma cells, respectively (Fujita *et al.*, 1989; Presgraves *et al.*, 2004).

Clonal cell lines are derived from the mitotic division of a single cell seeded in a sterile microtiter plate by limiting dilution as used in the cloning of hybridoma cell lines. Thus, cell lines can be cloned to exhibit a specific trait (e.g., high levels of specific receptors, drug resistance, etc.). While a homogeneous response to toxin treatment might then be expected from such a cell line, there is the risk of losing other features of a more heterogeneous population. In some cases, clones of transfected cell lines provide useful tools for mechanistic studies of cell differentiation and/or toxicity. For example, some cell cultures have been transfected with the certain cytochrome P450 transgenes to make them metabolically more competent during long-term studies (Tzanakakis *et al.*, 2002).

Primary cultures are derived by a combination of mechanical and enzymic disruption of the tissue of interest, which releases a collection of cells that resembles the tissue of origin closely both genetically and in terms of cell heterogeneity. It is then possible to enrich in specific cell types by using either selective culture media and/or cell growth inhibitors, immunomagnetic beads or fluorescence-activated cell sorting (FACS). If a monoculture is desirable (i.e., predominantly one specific cell type), the resultant culture would then need to be screened for cell-specific markers to determine purity/enrichment of the preparation, as a pure culture is rarely achieved. Typically, this would take the form of monitoring cultures for the expression of a unique morphological or molecular trait of the desired cell type to determine the level of enrichment. For example, expression of glial fibrillary protein (GFAP) and aster-like morphology would be good markers for astrocytic glial cells. Cells may be cultured as monolayers or, if a system simulating cell-cell interactions of the tissue of origin is required, cells may be cultured in suspension with mild agitation or using rolling cell culture. Under these circumstances, cells form clusters, spheroids or reaggregates that may continue to grow/proliferate over a period of several days or weeks, making them amenable to studies of long-term effects. For example, brain reaggregates prepared in this way have been maintained for up to several weeks and used in studies of pesticide toxicity (Sales *et al.*, 2000). However, many primary cultures tend to be very short lived. However, primary cell cultures do not necessarily exhibit identical cell-cell interaction patterns

as those in the tissue of origin and cell types that divide more rapidly could become more predominant than they would be *in vivo*.

A more recent development has been the use of stem cell lines as models for developmental toxicity testing (Hansen and Inselman, 2011). These cell lines are normally maintained in growth media containing mitogens, and can be induced to differentiate into different cell types (e.g., cardiomyocytes, pancreatic and neural cells) by removal of mitogens and/or the addition of specific trophic factors (Rolletschek *et al.*, 2004). Embryonic stem cells (ESCs) have the potential to differentiate into any cell type whereas progenitor cells are already committed to follow a specific developmental pattern. Alternatively, progenitor cell lines can be established; for example, neural progenitor cells can be induced to differentiate into a co-culture of neuronal and glial cell types, simulating the early stages and cell-cell interactions of neural development *in vivo* (Breier *et al.*, 2010). However, while stem cell cultures may represent excellent *in vitro* models for studying developmental toxicity, they are unlikely to exhibit identical cell-cell interactions and growth patterns as those in mature adult tissue.

One way to address this issue may be to develop a post-mitotic system containing pre-differentiated cells prior to the addition of toxin. However, this issue may be better addressed by using organotypic cultures. In this case, tissue slices (typically 200  $\mu$ m thickness) are cut from fresh tissue on a microtome, then subsequently rinsed and cultured in growth medium with agitation, as discussed above. Such slices maintain the complexity of cell-cell interactions and extracellular matrix composition of the original tissue and in some cases can survive up to several weeks (Sundstrom *et al.*, 2005). Nevertheless, even this kind of cellular system lacks the systemic interaction with the immune and circulatory systems that would occur *in vivo* and is not, therefore, a complete substitute for *in vivo* testing. However, using cell cultures as part of a tiered system of increasing complexity from *in vitro* to *in vivo* measurements would improve throughput, decrease costs and allow drastic reduction in the use of live animals in screening compounds for potential toxic effects. Some examples of *in vitro* toxicity testing systems in current use are indicated in Table 5.5.

### Endpoint determination for *in vitro* testing systems

A good *in vitro* testing system should be sensitive but at the same time yield low levels of false-positive and false-negative results. It should have endpoint measurements: that (1) show dose-response relationships for a given toxin, (2) reflect and are predictive of the *in vivo* pattern of toxicity for a given group of agents, (3) are objective

TABLE 5.5 Examples of cell culture systems used to model specific types of toxicity

Model	Description and comments
Neurotoxicity	Differentiating neural cell lines (e.g., human SH-SY5Y and rat PC12 neuroblastoma). Primary cultures, whole rat brain reagggregates and organotypic brain slice cultures (Sales <i>et al.</i> , 2000).
Hepatic toxicity	Human hepatoma HepG2 cell line and subclones expressing CYP1A1, cell lines engineered to express single human or animal P450, primary hepatocyte cultures, longer-term collagen sandwich cultures, liver slices and isolated perfused liver (Worth and Balls, 2002).
Developmental toxicity	Whole rat embryo cultures, rat limb bud reagggregates cultures and mouse embryonic stem cell lines (Liebsch and Spielmann, 2002). Standard operating procedures (SOPs) available on the ECVAM-INVITTOX databases.
Dermal toxicity	Keratinocyte and fibroblast cell lines. Excised rat skin models and human EPISKIN™ and EPIDERM™ skin models (Fentem <i>et al.</i> , 2001).
Immunotoxicity	Antibody production and activation/proliferation of lymphocytes (Karol, 1998).
Genotoxicity	Mammalian cell gene mutation and chromosome aberration tests (EPA, 1998i, j).

and reproducible, and (4) have internal controls. It is also useful if the testing system involves rapid assays of toxicity, allowing medium to high throughput analysis and simultaneous testing of multiple compounds and/or doses. The testing system should also be relatively inexpensive and involve technology and skills that are easily transferable to other laboratory personnel. Importantly, for a testing system to be deemed reliable for the prediction of acute *in vivo* human systemic toxicity it should have been validated through a rigorous international multi-center validation program. For example, during the period 1989–1996, 97 international laboratories tested the same reference chemicals (which represent different classes of chemicals with varied human toxicity) in their own *in vitro* systems. The outcomes of these studies are available on an Internet database (URL <http://www.cctoxconsulting.a.se/meic.htm>) and various aspects of the overall study have been published in eight articles in *Alternatives to Laboratory Animals*. Over the past 15 years or so, recommendations governing validation of *in vitro* alternatives, including systems for measuring chronic effects, have been published and are regularly reviewed by international organizations such as ECVAM (European Centre for Validation of Alternative Methods), ICCVAM (the Interagency Coordinating Committee on the Validation of Alternative Methods) and OECD. The interested reader is referred to the following articles for more recent publications on validated systems for toxicity testing (Liebsch and Spielmann, 2002; Bhogal *et al.*, 2005).

The best way to achieve something approaching an ideal testing system is to include a battery of endpoint measurements in order to minimize the occurrence of false-negative and false-positive results. Endpoint determination should give an objective assessment of a cytostatic, cytotoxic or other functional effect. It should also be quantitative or reproducibly qualitative. The selection of endpoints chosen should enable the categorization of toxins in terms of their toxicity relative to other agents of the same or other groups, giving reproducible results in different laboratory settings.

Endpoints can take a variety of forms, including measurements of cell viability, metabolic activity, morphology, changes in protein and gene expression and/or altered subcellular distribution of markers of interest. Some of the main endpoints are summarized below and the reader is referred to Masters (2000), the INVITTOX (<http://www.invittox.com/>) and ECVAM (<http://ecvam-dbalm.jrc.ec.europa.eu/>) websites for further information and technical details about specific protocols and validated models used in toxicity testing *in vitro*.

### Cell viability

The traditional method of determining cell viability is to determine the cell density (cells/ml) in a hemocytometer chamber. While this is a very useful method for determining cell number for seeding in cell culture experiments, it does not distinguish between viable and non-viable cells following exposure to toxin. However, the proportion of non-viable cells can be determined in parallel by assessing the percentage of counted cells that take up the dye Trypan blue, which is excluded from viable cells. Though effective, this approach is not suited to high throughput, as measurement can be time consuming and is therefore best suited to small numbers of samples or treatments.

An alternative approach is to use dye uptake assays. For example, neutral red accumulates on the lysosomes of viable cells, after which it can be extracted from cells with an organic solvent and determined spectrophotometrically. A variation on this is to prelabel cells with the dye prior to treatment with toxin; reduced levels of absorbance compared to untreated control cells would be indicative of dye release due to membrane damage.

Appropriately equipped laboratories might choose to use a dual fluorescence assay to determine the proportion of live and dead cells. In one such system, fluorescein diacetate is taken up by viable cells and cleaved by intracellular esterases to release fluorescein producing green fluorescence in the cytoplasm, whereas propidium iodide only crosses the membrane of damaged cells and

stains the nucleus (DNA) producing red fluorescence (Coder, 1997). Specimens are observed using a fluorescence microscope and quantification can be achieved by image analysis or by FACS analysis.

### *Membrane leakage*

Leakage of macromolecule through the plasma membrane into the culture medium is an effective means of detecting early or late stages of membrane damage. Cells can be incubated in the presence of  $^3\text{H}$ -thymidine, which is incorporated into DNA during cell proliferation. Subsequent loss of  $^3\text{H}$ -labeled DNA would be indicative of cell lysis. An alternative approach is to label cells in the presence of  $^{51}\text{Cr}$  which binds to many cellular proteins. Loss of labeled proteins from treated cells would be indicative of membrane leakage/cell lysis. In this sense the  $^{51}\text{Cr}$  release assay is more sensitive than that for  $^3\text{H}$ -labeled DNA as the former will detect signs of damage to the membrane at a much earlier stage than the latter.

An attractive alternative to radioisotopic methods is the release of lactate dehydrogenase (LDH) into cell culture medium, which is measured spectrophotometrically. The assay shows sensitivity comparable to the  $^{51}\text{Cr}$  release assay and is amenable to microtiter plate format, which would facilitate medium to high throughput analysis.

### *Cell growth and proliferation*

Cell growth or proliferation can be measured in a number of ways.

#### *Cloning efficiency*

In the absence of sophisticated equipment, perhaps the simplest method is that of cloning efficiency. In this case, cells would be plated at a density of 100–200 per culture vessel and assessed microscopically for their ability to produce viable colonies after a given period of incubation in the presence and absence of toxin. This is one of the most sensitive methods used for testing the effects of toxins on the growth of mitotic cells.

#### *Mitogenicity*

This can be determined in a number of ways. For example, the mitotic index of cell cultures can be determined by counting the percentage of mitotic figures following staining of DNA with hematoxylin. Alternatively, the proportion of cells in S-phase can be determined by immunohistochemical staining of cells incubated with the thymidine analog 5-bromo, 2-deoxyuridine.

#### *DNA synthesis*

Another approach is the measurement of cell growth in toxin-exposed cells via the incorporation of

$^3\text{H}$ -thymidine into DNA (Flaskos *et al.*, 1994). This method gives a good quantitative assessment of the effects of toxins on cell proliferation, as the radioisotope is incorporated into cells during S-phase of the cell cycle. High throughput analysis requires the use of a cell harvester to lyse cells and transfer radiolabeled DNA onto filters prior to detection by scintillation counting. Alternatively, cell proliferation can be measured by the incorporation of 5-bromo, 2-deoxyuridine incorporated into S-phase cultured cells, and subsequent quantification by enzyme-linked immunoabsorbent assay (ELISA) (Lanier *et al.*, 1989). Total DNA content can also be determined by detecting fluorescence after incubation of cells with DNA binding dyes such as Hoechst 33258, using a spectrofluorimetric microplate reader or by FACS analysis (Downs and Wilfinger, 1983).

#### *Protein synthesis*

Cell growth can also be measured by total protein content or by protein synthesis. Protein content can be estimated by a number of dye binding assays in microtiter plate format, such as the bicinchoninic acid (BCA) assay (Tuszynski and Murphy, 1990). More rapid analysis can be achieved by fixing and staining cells directly with Coomassie brilliant blue. After washing, the dye is solubilized and the absorbance of protein bound dye measured spectrophotometrically. As a measure of total protein synthesis, cells can be incubated in the presence of radiolabeled amino acids such as  $^{35}\text{S}$ -methionine or  $^{14}\text{C}$ -leucine and TCA precipitable protein assessed for radioactive content by scintillation counting. If an assessment of specific protein changes is required, protein extracts can be separated by polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate (SDS-PAGE) and proteins stained with Coomassie blue or another protein staining dye. Changes in radiolabeled protein synthesis, which could be masked by the pre-existing protein pool, can be detected by autoradiography following exposure of dried gels onto X-ray film.

#### *Cell morphology*

Changes in cell morphology can be measured microscopically and are very useful in studies of mechanisms of toxicity. However, medium to high throughput analysis of toxicity would require the use of image analysis software to produce more consistent data. Specialist techniques such as Allen video-enhanced contrast differential interference contrast (AVEC-DIC) microscopy facilitate analysis of effects on living cells. Furthermore, high throughput assays could be developed that measure the underlying molecular changes determined from follow-up studies.

Morphological changes can take various forms, as indicated below.

### *Cell volume*

An increase or decrease in cell volume could indicate osmotic changes or may represent the early stages of cell death by necrosis or apoptosis. Cell death or viability changes would then need to be made to confirm the type of cell death occurring, as indicated earlier.

### *Cell shape*

Changes in shape may occur following exposure to a toxin. These could include rounding up, flattening, spreading or process outgrowth in cell culture monolayers. Such changes would give an initial indication of altered cell attachment, migration, proliferation or differentiation, indicating potential targets for follow-up molecular studies. For example, OP-induced changes in axon outgrowth in cultured neurons indicated possible changes in proteins associated with axon growth and maintenance, which were then targeted in molecular studies (Hargreaves *et al.*, 2006).

### *Membrane integrity*

Changes in membrane integrity may be indicated by surface blebbing, which can occur as a result of cellular stress (e.g., oxidative stress) or during the early stages of apoptosis. These parameters could be measured further by biochemical methods to confirm the underlying molecular events associated with these morphological changes (e.g., free radical generation, lipid peroxidation, caspase activation, etc.).

### *Growth patterns*

Growth patterns may change as a result of exposure to toxin. Thus, the proportion of cells growing in colonies or singly would indicate changes in cell-cell interactions and potential changes in cell adhesion proteins, which could be targeted in subsequent molecular studies.

### *Metabolic assay*

#### *ATP levels*

ATP is an essential requirement for many energy-dependent processes and its levels can be affected by a variety of toxins. It can be used as a marker for cell viability as it is present in all metabolically active cells and its levels decline rapidly when cells undergo apoptosis or necrosis (Kangas *et al.*, 1984). A number of reagents and kits suitable for high throughput screening are available. Typically, the amount of ATP in cell lysates is determined by the light released from firefly luciferase-catalyzed oxidation of D-luciferin in the presence of ATP and oxygen. ATP and its major metabolites (ADP and AMP) in cell culture extracts can also be determined using an HPLC method (Yang and Gupta, 2003).

### *Dehydrogenase activity*

The activity of cellular dehydrogenases can be assayed by the reduction of the yellow methyl tetrazolium dye to its blue formazan reaction product. The reduced dye forms crystals in metabolically active cells and, after removal of growth medium, can be solubilized in an organic solvent such as dimethyl sulfoxide and quantified spectrophotometrically in microtiter plate format, for example in assays of *in vitro* toxicity of OPs (Hargreaves *et al.*, 2006).

Although metabolic assays such as those indicated above are not direct measurements of cell viability, a significant fall in either measurement is normally taken to indicate a fall in cell viability or cell number.

### *Calcium homeostasis*

Many toxins have a direct or indirect effect on mechanisms involved in the control of  $\text{Ca}^{2+}$  homeostasis. Such effects could be related to a breakdown in plasma membrane integrity, which would also be detected by other methods discussed previously (e.g., leakage of LDH), or it may be the result of a selective effect on  $\text{Ca}^{2+}$  channels or  $\text{Ca}^{2+}$  ATPases that regulate  $\text{Ca}^{2+}$  movements across cellular membranes. Changes in  $\text{Ca}^{2+}$  flux can be measured using a variety of  $\text{Ca}^{2+}$  binding dyes that fluoresce when bound to  $\text{Ca}^{2+}$  (e.g., Quin 2 and Fura 2). Detection requires spectrofluorimetric analysis which is potentially applicable to high throughput analysis of average change for a given cell population. However, analysis of changes in  $\text{Ca}^{2+}$  flux in individual cells requires a system that has an integrated microscope and image analysis software package.

### *Cell or tissue specific markers of toxicity*

This approach is useful for targeting key proteins or enzyme activities involved in the normal function(s) of the target cells or tissues. It is particularly useful in sub-lethal/ chronic studies of exposure to toxin, in order to determine whether a potentially reversible functional deficit occurs. The principal approaches used at the protein level are those of antibody-based detection and enzyme assays.

#### *Antibody-based detection*

This involves mainly immunoblotting techniques such as Western blotting and dot blotting coupled with densitometric analysis of antibody reactivity with target antigens. In Western blotting the cell extracts are normally denatured, separated by SDS-PAGE and transferred electrophoretically onto nitrocellulose membrane filters (Towbin *et al.*, 1979) thus creating a replica of the gel pattern that is more accessible to antibody probes. By contrast, in dot blotting an extract is applied directly in a circular dot onto the membrane filter, without

chromatographic separation of proteins. Alternatively, experiments could be carried out on microtiter plates and the levels of antigens of interest determined in fixed cell monolayers by ELISA. Changes in the cellular or tissue distribution of antigens of interest can also be determined by immunohistochemical staining methods using enzyme-conjugated or fluorophore-conjugated antibody detection systems in a light microscope or fluorescence microscope, respectively. In the case of fluorescence microscopy quantification of antigen levels or distribution can be done with the aid of image analysis software. These approaches have been used effectively in mechanistic studies of OP toxicity (Hargreaves *et al.*, 2006).

#### Enzyme assays

Many cells and tissues can be monitored by the activity of enzymes that are known targets of the xenobiotics in question. For example, as discussed earlier, AChE activity is a good indicator of the acute neurotoxic effects of cholinesterase inhibitors such as OPs and carbamates *in vitro*, whereas NTE is a marker of the delayed neurodegenerative capability of OPs (Ehrich *et al.*, 1997). There are also enzymes that provide useful markers of specific cell types, such as tyrosine hydroxylase for dopaminergic neurons (Kuhn and Geddes, 2000), 2',3'-cyclic nucleotide 3'-phosphohydrolase for glial cells (McMorris, 1977) and alanine aminotransferase for hepatocytes (Amacher *et al.*, 1998). Where possible, changes in expression of the enzyme should also be taken into account when interpreting specific activity data.

#### Proteomic analysis

This approach can be useful in mechanistic studies of toxicity as it helps to identify novel protein markers of toxicity. Techniques of this type include the use of two-dimensional PAGE, chromatographic or protein chip fractionation of proteins from cell/tissue lysates or subcellular in order to identify changes in specific protein levels following toxin exposure. Proteins of interest are then normally digested with trypsin and the tryptic fragments are initially identified by "peptide mass fingerprinting" in a matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectrometer, followed by further confirmation using, e.g., tandem mass spectrometry (MS-MS) (Steen and Mann, 2004). Identification is facilitated by the use of freely available Internet-based gene and protein sequence databases such as MASCOT, SwissProt, etc.

#### Genomic analysis

Changes in the levels of specific proteins detected by proteome analysis could reflect changes in the regulation of protein turnover (i.e., how rapidly it is degraded

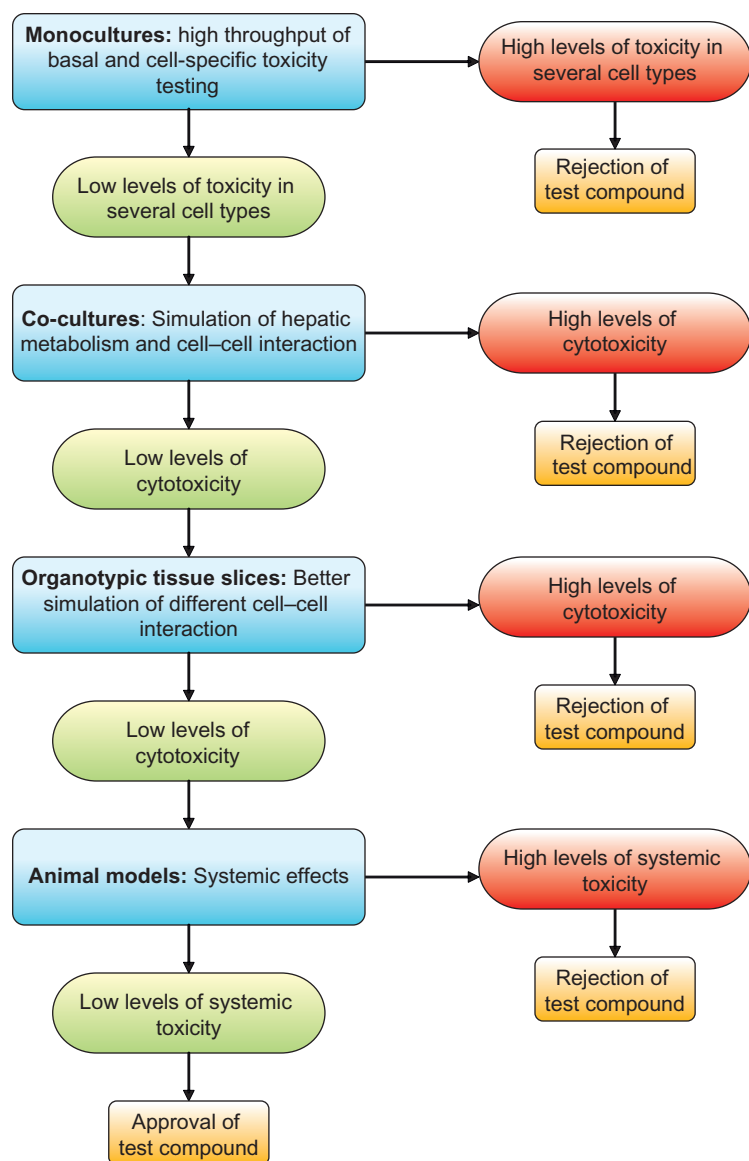

once synthesized) or changes in gene expression. Furthermore, depending on the cell or tissue fractionation procedures adopted, changes in low abundance proteins that could be functionally important may not necessarily be detected by proteomic methods. Changes in gene expression following exposure to toxin can be determined by a number of methods including reverse transcriptase polymerase chain reaction (RT-PCR) and DNA microarray analysis (Koizimo and Yamada, 2003).

RT-PCR is a targeted approach involving the production of complementary DNA (cDNA), by treatment of cell or tissue RNA with RT. The resultant cDNA is then incubated with primers (probes) that recognize specific genes or DNA sequences of interest, followed by amplification of such sequences by the Taq polymerase reaction. Changes in the level of amplified target sequence would indicate corresponding changes in the expression of the target gene to which the primers are matched. This approach is only semi-quantitative although accuracy can be improved by continuous measurement of amplicon levels using real-time RT-PCR. Levels of amplicon are normally compared to changes in household genes such as glyceraldehyde dehydrogenase, as an internal control.

A less targeted approach that, nevertheless, could help to identify novel changes in gene expression is that of DNA microarray analysis. In this technique, up to several thousand genes are immobilized on a template and probed with labeled RNA from control and treated cells or tissues. Image analysis software is then used to determine up- or down-regulation of genes due to toxin exposure. Controls usually involve averaged changes for a series of household genes. The researcher should be aware that a change in levels of gene expression does not necessarily indicate a corresponding change in protein levels or vice versa, as there are multiple levels of control. A multi-disciplinary approach is recommended to get an accurate overall picture of the chain of events following exposure to toxin.

## GENERAL SUMMARY AND CONCLUSIONS

A major issue facing toxicological science today is how to convert experimental data from *in vivo* and *in vitro* models into knowledge about molecular mechanisms of toxicity and safe levels of exposure to the agents tested. A number of animal models that have been used for many years for screening purposes have been gradually refined with increasing emphasis on improved experimental design, animal welfare and reduced animal use. More recent developments in the area of *in vitro* toxicity

**FIGURE 5.3** Flow chart showing principles of multi-tiered approach to toxicity testing.

testing have contributed significantly to the gradual reduction in animal use for toxicity screening and have helped to improve knowledge relating to mechanisms of cell- or organ-specific toxicity. Veterinarians have played an important role in the development of legislation and guidelines relating to the use and replacement of laboratory animals in toxicity assessment.

The generally accepted approach to screening compounds for toxicity is to use a multi-tiered system starting with simple monocultures of specific cell types, followed by co-cultures that simulate metabolic effects and/or cell-cell interactions in the whole organism, before carrying out final testing on animals (Figure 5.3). In this way, it is possible to eliminate compounds that exhibit high levels of basal toxicity in several cell types and reduce unnecessary suffering in animals. In both *in vitro* and *in vivo* testing it is important to use a battery of

appropriate endpoint measurements of both basal toxicity and cell/tissue-specific toxicity at each level, in order to increase the reliability and predictive potential of the data produced.

*In vitro* toxicology has made significant advances in the last few decades, by improving and finding solutions to its limitations. For example, cell culture systems are now being designed to be metabolically competent and viable for several weeks, making them appropriate not only for short- but also for long-term toxicity testing (Bhogal *et al.*, 2005). Extending this approach to a wider range of cell culture systems will improve the prospect of using *in vitro* methods for studying a wider range of chronic toxicological phenomena. However, further development and validation of *in vitro* models is required if they are to be adopted on a much wider scale in order to secure further reduction, replacement and

refinement of animal models. This will require further improvements in cell culture technology and growth conditions, such as the increased use of hollow fiber systems to facilitate continuous replenishment of media and supplements (Nussler *et al.*, 2001). The increased use of microsomal activation systems and/or established cell lines transfected with genes for mixed function oxidases is another approach that will help to increase the metabolic competence of *in vitro* models. Another promising *in vitro* approach involves the use of adult or embryonic stem cells of human or rodent origin. These cells can be either continuously cultured without being differentiated or they can generate a wide variety of functional mammalian cell types. In addition to its application in developmental toxicity testing, stem cell technology has been successfully used to study mechanisms of toxicity and to screen new pharmaceutical compounds for teratogenicity, genotoxicity, hepatotoxicity and cardiotoxicity (Davila *et al.*, 1998, 2004).

The development of medium to high throughput methods in proteomics, genomics and metabolomics, together with the revolution in bioinformatics, will lead to the accumulation of vast toxicological information, helping to elucidate mechanisms of toxicity in both *in vitro* and *in vivo* models (Bhogal *et al.*, 2005). These approaches will also help in the development and establishment of new biomarkers of effect or exposure.

In conclusion, although it is a desirable goal to replace all animal testing, animal-based toxicological testing is likely to continue for the foreseeable future. Further improvements in animal models will make them more reliable indicators of human toxicity, while the development of improved *in vitro* systems will eventually minimize the use of animals for toxicity studies. The veterinarian's role will therefore be to continue monitoring and improving the welfare of animals used in toxicity testing and to advise on issues relating to the development of *in vitro* alternatives.

# Epidemiology of animal poisonings in the United States

Sharon M. Gwaltney-Brant

## INTRODUCTION

Although animals are exposed to potentially toxic agents on a daily basis, actual poisoning cases are uncommon when compared to other conditions of veterinary concern (infectious disease, trauma, metabolic disease, neoplasia, etc.). Clients will often present their animal with a suspicion of poisoning, only for the veterinarian to determine that the animal is suffering from an unrelated ailment. When evaluating information regarding suspected poisoning cases, it is important to consider the full exposure and patient history before determining whether a particular exposure is related to a clinical syndrome, as temporal coincidence does not necessarily equal causality.

The fundamental rule of toxicology as stated by Paracelsus, considered to be the “Father” of toxicology, is “the dose makes the poison.” Obviously the dose required to induce toxicosis will depend on a variety of factors, including the agent in question, species of animal exposed and route of exposure. Based on information from poison control centers, the majority of animal exposures to potentially toxic agents result in no signs developing (Hornfeldt and Murphy, 1992; Forrester and Stanley, 2004). However, clinically significant animal poisonings do occasionally occur from exposures to natural or man-made hazards. Knowledge of the most common features of animal poisonings can aid in instituting measures that may help to minimize exposures of animals to toxicants.

## BACKGROUND

The lack of a central reporting agency for animal poisonings makes epidemiological study difficult. With no mandated reporting, many suspected poisoning cases are managed by the attending veterinarian and forgotten. Confirmatory testing at veterinary diagnostic laboratories is not common, and no central mechanism exists for these laboratories to report their findings for epidemiological analysis. Most published information on animal poisonings has largely come from human or animal poison control centers that animal owners have contacted regarding potential exposures to toxic agents (Haliburton and Buck, 1983; Hornfeldt and Borys, 1985; Hornfeldt and Murphy, 1992, 1997, 1998; Forrester and Stanley, 2004) or from surveys of veterinary emergency centers or teaching hospitals (Osweiler, 1975; Cope *et al.*, 2006). Data from these sources can be helpful in determining trends and identifying emerging toxicants, but because of the frequent lack of complete historical information and confirmatory testing, care must be taken in the interpretation of each case of suspected poisoning.

Forrester and Stanley (2004) reported that exposures of animals to toxicants occurred more commonly in the summer, and this is consistent with data from the ASPCA Animal Poison Control Center’s AnTox™ database (Figure 6.1), although a peak in December, associated with the holiday season, is also present in the APCC data (ASPCA Animal Poison Control Center, unpublished data, 2010). The uptick in cases in the spring with

FIGURE 6.1 Monthly distribution of cases managed by ASPCA Animal Poison Control Center in 2010 (unpublished data).

peak cases during the summer is likely due to a variety of factors. Domestic animals tend to be more confined during the winter, particularly indoors, limiting their access to potentially toxic agents. Toxic plants and animals are not frequently encountered during the winter months, making exposures to these potentially poisonous entities unlikely. With the advent of warmer spring weather, domesticated animals have more access to outdoors and the plants, insects and other animals that reside there. The use of agents such as fertilizers, insecticides and herbicides also increases during these months, increasing the risk of animal exposures to these agents. Cool, wet, spring weather favors the rapid appearance of potentially toxic mushrooms, while hot summer weather can trigger growth of toxic blue-green algae in water. Other seasonal influences on the incidence of animal exposures to toxicants include increased presence of rodenticides in late fall as rodents begin to move indoors in response to cooling temperatures, increased use of psoriasis medication (e.g., calcipotriene) during winter months, increased use of ice-melting agents in winter, increased presence of lilies in the spring (Easter, Mother's Day), and increased presence of chocolate around the holidays of Valentine's Day, Easter, Halloween and the November–December holidays (Hautekeete, 2000; Gwaltney-Brant, 2001; Volmer, 2001; Merola, 2002).

The majority (>90%) of animal poisonings are accidental, acute in nature and occur near or at the animal owner's home (Hornfeldt and Murphy, 1992, 1998; Khan *et al.*, 1999). Malicious intent comprises less than 1% of all exposures to potentially toxic agents. The majority (70–95%) of exposures is due to acute ingestion, followed by acute dermal exposures (Hornfeldt and Murphy, 1992; Forrester and Stanley, 2004). Inhalation, envenomation, bites, ocular and parenteral routes of exposure

account for less than 1% and chronic exposures comprise approximately 1% of all reported cases. In 97% of exposures, a single agent is involved (Hornfeldt and Murphy, 1992, 1998).

## DEMOGRAPHICS

Based on data from human and animal poison control centers, dogs and cats are the species for which owners most frequently seek assistance with potential poisonings, accounting for 95–98% of all reported animal cases (Hornfeldt and Murphy, 1998; Xavier *et al.*, 2002; Forrester and Stanley, 2004; Giuliano Albo and Nebbia, 2004). Approximately 2–5% of reported animal poisoning cases involved other species of domesticated animals, exotic animals and wildlife. These percentages have changed considerably since 1983, when dogs and cats accounted for 44% of calls to an animal poison control center, with production animals (bovine, porcine, ovine) and equines making up 35% of calls (Trammel *et al.*, 1985).

## DOGS

Perhaps at least partly because of their inquisitive natures and willingness to investigate everything with their mouths, dogs far outrank other species when it comes to owners seeking aid for potential poisonings, making up 70–80% of all animal cases reported (Hornfeldt and Murphy, 1992, 1998; Xavier *et al.*, 2002; Forrester and Stanley, 2004; Berny *et al.*, 2009). There is

a tendency in the veterinary community to consider certain breeds, such as Labrador retrievers, to be more prone to exposure to potentially toxic agents. However, to verify such an impression, one must take into account the relative popularity of a particular breed. In other words: Are there more poisoning cases with Labrador retrievers because they really are more inclined to misadventure, or is it just that there are more Labrador retrievers in the population? A survey of the APCC database in 2005 (ASPCA Animal Poison Control Center, unpublished data, 2005) evaluated over 68,000 exposures of non-mixed breed dogs and compared the relative breed incidence to the 2005 Registration Statistics reported

by the American Kennel Club, the oldest and largest purebred dog registry in the United States (American Kennel Club (AKC), 2006). The results of this comparison are displayed in Table 6.1 and the top 20 breeds are compared graphically in Figure 6.2. In 2005, Labrador retrievers accounted for approximately 15% of AKC registered breeds, with almost three times more registered than the next most popular breed, the golden retriever. During the same year Labrador retrievers accounted for 17.5% of canine exposures in APCC cases, which was also three times more than the next most popular breed (the golden retriever) and which was not significantly different from the AKC statistics. In analyzing the data in

TABLE 6.1 Comparison of purebred dog breeds in relation to frequency of exposures to potentially toxic agents reported to the ASPCA Animal Poison Control Center with the relative popularity of the breed based on registration statistics from the American Kennel Club during 2005

ASPCA Animal Poison Control Center, unpublished data (2005) and American Kennel Club (2006).

Table 6.1, a few breeds did appear to be over-represented in regards to exposures to potentially toxic agents. For instance, the Bichon Frise ranked 26th in AKC registrations yet ranked 15th in the APCC data, occurring in APCC cases (2.1%) at twice the incidence of AKC (1%); Welsh springer spaniels made up 0.03% of AKC registered dogs, but accounted for 0.18% of APCC dogs. However, care must be taken when evaluating the data from certain breeds (such as greyhounds, border collies and Parson Russell terriers), as many individuals of these breeds are registered with their own independent breed registry rather than the AKC; this may be one reason why all three of these dog breeds appear over-represented in APCC data.

Comparison of 2005 and 2010 APCC data shows that Labrador and golden retrievers still top the list of breeds involved in calls regarding potential poisonings in 2010 (ASPCA Animal Poison Control Center, unpublished data, 2005, 2010). Rounding out the top 10 breeds for 2010 poisoning calls, in descending order, are Chihuahua, Yorkshire terrier, Shih tzu, miniature Dachshund, Boxer, Beagle and American pit bull terrier. German shepherd dogs, which ranked 3rd in 2005, ranked 11th in 2010, although they were 2nd in 2010 AKC Registrations.

Previous reports of poisoning cases in dogs have indicated no gender predisposition, and most reports indicate that adults are most commonly involved, with an average age of approximately 4 years (63.6 years)

**FIGURE 6.2** Comparison of top twenty purebred dog breeds in relation to frequency of exposures to potentially toxic agents reported to the ASPCA Animal Poison Control Center with the relative popularity of the breed based on Registration Statistics from the American Kennel Club in 2010 (ASPCA Animal Poison Control Center, unpublished data, 2010).

(Khan *et al.*, 1999; Cope *et al.*, 2006). Given the wide age ranges in these studies (0.15–15 years) and the relatively low average age, it would appear that young adult dogs are most inclined to be exposed to potentially toxic agents. Reports of canine poisonings in Europe indicate that young dogs are at increased risk, with dogs 2 years of age and under comprising half or more of poisoning cases (Berny *et al.*, 2009).

## CATS

Due, perhaps, to their more discriminating habits and appetites, cats account for only 11–20% of reported animal exposures to potential toxicants, which is three times less frequent than dogs (Hornfeldt and Murphy, 1992, 1998; Xavier *et al.*, 2002; Forrester and Stanley, 2004, Berny *et al.*, 2009). In 2010, 71% of cats exposed to potential toxicants were identified as domestic (or American) shorthairs, 8% as domestic longhairs and 6% as domestic mediumhairs (ASPCA Animal Poison Control Center, unpublished data, 2010). Excluding these types of cats

due to the generic nature of their classification, the top 10 purebred cats were Siamese (24%), Main coon (15%), Persian (10%), Himalayan (8%), Ragdoll (6%), Bengal (6%), Russian blue (3%), Abyssinian (3%), Manx (2%) and Siberian (2%). Of these, the Persian, Maine coon, Siamese, Abyssinian and ragdoll are listed in the 10 most popular breeds registered by the Cat Fancier's Association in 2010 (CFA, 2010). As with dogs, no gender or age differences in incidence of exposure have been noted. Cats may, due to their grooming habits, be more susceptible to toxicants that come into contact with their fur; this is especially problematic with agents to which cats are exquisitely sensitive (e.g., ethylene glycol).

## OTHER SPECIES

Demographic information on potential poisonings in animal species other than dogs and cats in North America is largely lacking. Production animals are generally kept in large groups, meaning that when a toxicosis occurs, there is potential for multiple animals of varying age and genders to be exposed. Most production animals are kept in some form of confinement, which limits the potential for exposure to toxic agents. However, mistakes in management, such as feed mixing errors or improper ventilation, may result in acute or chronic toxicosis in large numbers of animals. A study of livestock poisonings in Greece indicated that sheep were the commonly poisoned species, attributed primarily to their ingestion of potentially contaminated soil (Guitart *et al.*, 2010a).

Wildlife is almost continuously exposed to toxic agents in the environment, but specific demographic information is not available in most cases. In France, birds are reported to be more commonly poisoned than mammals (Guitart *et al.*, 2010b). Seasonality of poisoning incidences in wildlife would vary with the agent involved. For instance, avian botulism in waterfowl tends to be seasonal, with most cases occurring between the months of July and September (Locke and Friend, 1989). In addition to naturally occurring toxicants, exposures to man-made hazards (e.g., oil spills, industrial effluents) can result in significant wildlife morbidity and mortality.

## AGENTS INVOLVED

There is an unlimited number of agents by which exposed animals may become poisoned, and for the most part, which specific agents are involved in animal poisonings will be dependent upon what is available in the animals' environment, the potential or inclination

**TABLE 6.2** Exposures of animals to various toxic agents reported by veterinary clinics and poison control centers, 1975–2006

Agent	1975	1978–1981	1990	1993	2006
Chocolate	NR	NR	NR	NR	26%
Glycols	1%	NR	10%	NR	4%

Pesticides <sup>++</sup>	23%	20%	21%	21%	13%
Pharmaceuticals	NR	10%	25%	24%	22%
Plants	1%	12%	2%	10%	5%
Rodenticides	27%	7%	14%	7%	26%

NR: not reported; ++: combined insecticide and herbicide exposures. Osweiler (1975), Haliburton and Buck (1983), Hornfeldt and Murphy (1992, 1998) and Cope *et al.* (2006).

for the animal to be exposed to the agent, the amount of agent to which the animal is exposed, and the individual sensitivity of the animal to the effects of the agent. The potential for exposure to specific agents may be uniform throughout the year or may be seasonal, depending on the agent and the species involved. For instance, exposures to lawn care products, such as herbicides and insecticides, would be expected to be more common during the seasons when these products are most in use (i.e., spring and summer).

Table 6.2 summarizes the most common agents involved in animal exposures reported to veterinary emergency referral centers and human or animal poison control centers in the United States. These exposures predominantly involve companion animals, particularly dogs and cats, and are consistent with the types of animal exposures reported by poison control centers in other countries (Xavier *et al.*, 2002; Giuliano Albo and Nebbia, 2004).

Rodenticides, pharmaceuticals and chocolate make up the majority of agents in the most recent report summarized in Figure 6.3 (Cope *et al.*, 2006). Rodenticides and chocolate made up approximately one quarter of all exposures, followed by pharmaceutical agents, which accounted for 22% of exposures. Pharmaceutical exposures have increased since first reports in 1983 (Beasley and Trammel, 1994), likely due to the increased use of these agents in veterinary and human medicine over the past 20 years. The most common pharmaceutical agents associated with animal exposures are analgesics (primarily non-steroidal anti-inflammatory drugs) and central nervous system drugs (sedatives, antipsychotics, stimulants, etc.) (Hornfeldt and Murphy, 1992, 1998). None of the reported data from poison control centers included information specifically on chocolate cases, but a veterinary emergency hospital reported that exposure of dogs to chocolate accounts for one in every four presentations for potential toxicosis (Cope *et al.*, 2006). Pesticides have historically been responsible for large numbers of exposures and toxicoses in domestic animals (Beasley and

**FIGURE 6.3** Most common agents involved in canine exposures presenting to a veterinary emergency center in 2006 (Cope *et al.*, 2006).

**FIGURE 6.4** Comparison of incidence of animal exposures to pesticides reported to human poison control centers and veterinary clinics (Osweiler, 1975; Haliburton and Buck, 1983; Trammel *et al.*, 1985; Hornfeldt and Murphy, 1992).

Trammel, 1994), but the incidence appears to be declining (Figure 6.4). This may be due in part to the development of newer herbicides and insecticides that have a much higher margin of safety in mammals than those used in the past, as well as perhaps better public awareness of the potential hazards of these agents to pets.

Less information is available regarding exposure of non-canine and non-feline animals to potential toxicants. For livestock, plant poisoning causes tremendous economic losses to producers, estimated to exceed \$350 million per year (Galey, 1996). Losses from poisonous plants are due to deaths as well as loss of productivity. Other agents reported to be responsible for significant livestock loss include mycotoxins, organophosphate and carbamate insecticides, nitrate and lead, although lead poisoning appears to be on the decline in livestock. For waterfowl, avian botulism is a concern, resulting in the loss of thousands to millions of birds each year (Locke and Friend, 1989). Lead toxicosis was once a significant cause of loss of waterfowl in the United States due to ingestion of lead shot left by hunters, but the incidence of lead toxicosis has decreased following an enforced

ban on the use of lead shot on waterfowl (Gwaltney-Brant, 2004). However, lead intoxication still occurs in raptors that ingest upland prey that have shot embedded in their tissues. Wild animals ingesting the tissues of animals that have been euthanized with barbiturates are at risk of toxicosis (Hayes, 1988), and toxicosis has been reported in a variety of species feeding on animals intentionally poisoned with pesticides (Stroud, 1998; Wobeser *et al.*, 2004). The use of non-steroidal anti-inflammatory drugs in livestock has been linked to the marked decline in vultures and other scavenging birds in India, Asia and Africa (Naidoo *et al.*, 2009, 2010). Intentional poisoning of wildlife with pesticides is most commonly accomplished using carbofuran and aldicarb, while accidental or secondary poisoning of wildlife by pesticides most often involves strychnine, famphur, fenthion and avitrol (Stroud, 1998). Oil spills near sea shores have resulted in significant loss of life of animals living in or around these areas, and industrial pollution from agricultural or industrial effluents has similarly caused deaths in a variety of wildlife species.

## SIGNS AND OUTCOMES

Based on poison control center statistics, the majority (57–63%) of animal exposures to potential toxicants result in no signs for the patient, due either to insufficient level of exposure or successful decontamination by animal caretakers (Figure 6.5). Mild signs developed in 25–27% of animal exposures to suspected toxicants, moderate signs developed in 7–8%, major signs developed in approximately 1% and death occurred in 2–3% of cases where outcomes were known (Hornfeldt and Murphy, 1992, 1998). Mild signs are those in which some clinical signs developed but are expected to be mild and self-limiting and not in need of treatment (e.g., hypersalivation, mild vomiting, etc.). Moderate signs are those in which signs that develop are more pronounced, prolonged or of a systemic nature and merit some form of treatment, although the signs would not be expected to be life-threatening (e.g., protracted vomiting, severe diarrhea, mild to moderate hypotension). No residual effects would be expected following recovery. Major signs are those in which life-threatening conditions exist or there is potential for significant residual disability or disfigurement following recovery from the acute episode (e.g. seizures, renal injury, etc.).

Agents most frequently reported to be associated with mild to moderate signs in animals are pharmaceuticals (19%), pesticides (insecticides and herbicides, 14%), plants (10%), cleaning products (8%) and mushrooms (3%) (Hornfeldt and Murphy, 1998). Agents associated with major signs included pesticides (45%),

FIGURE 6.5 Degree of illness in animals following exposure to potentially toxic agents (Hornfeldt and Murphy, 1992, 1998).

pharmaceuticals (25%), plants (15%), rodenticides (9%) and cleaning products (8%). Deaths were most commonly associated with exposures to pesticides (24%), pharmaceuticals (17%), rodenticides (16%), plants (9%), automotive products (predominantly ethylene glycol, 9%) and cleaning products (8%). Organophosphate insecticides, ethylene glycol and long-acting anticoagulant rodenticides were the top three agents responsible for deaths in animals.

## CONCLUSIONS

Poisonings are a serious cause of morbidity and mortality in animals, particularly in dogs and cats. Based on information obtained by veterinary clinics and human and animal poison control centers the incidence of animal poisoning does not appear to be waning, although the agents to which animals are exposed do change with time. While significant pesticide exposures may be on the decline due to the development of newer and less toxic pesticides, exposures to other agents, such as chocolate and pharmaceutical agents, may be on the rise. Knowing what agents have the potential to be involved in serious toxicoses should allow veterinarians to better educate their clients on means of preventing animal poisonings through the appropriate use of household products and the removal of potential hazards from the animals' environments.

# Epidemiology of animal poisonings in Europe

Francesca Caloni, Philippe Berny, Siska Croubels, Magda Sachana and Raimon Guitart

## INTRODUCTION

A centralized veterinary poison control/information center does not exist in the EU. In many countries information related to animal poisoning is unavailable (BG, CY, EE, HU, LT, LV, MT, PT, RO, SI, SK) or inadequate (DK, LU) and refers only to isolated case reports when it does exist. Occasionally, epidemiological data on animal poisoning gathered by universities, research institutes, government institutions or independent laboratories has been published in the last decade in AT, DE, EL, ES and IT (see [Table 7.1](#) for country abbreviations).

In certain countries such as CZ, EL, ES, FI, IE, IT, NL, PL and SE, human poison control centers collect data on animals also. In IT, the Servizio di Assistenza Tossicologica Veterinaria (SATV) used to provide telephone assistance in cases of small animals only ([Giuliano Albo and Nebbia, 2004](#)), whereas the Assistenza Tossicologica Veterinaria (ATV) is now in operation. In BE, the Belgian National Poison Center in Brussels (BPC) holds a 24-hour hotline for suspected human and animal poisoning. The Laboratory of Toxicology of Ghent University (LTGU) and the Centre d'Informations Vétérinaires en Pharmacotoxicologie, Université de Liège, are specialized in analytical confirmation of animal poisoning for the northern and southern parts of BE, respectively ([Vandenbroucke et al., 2010](#)).

Centers in the EU exclusively dedicated to animal poisoning are located in FR and in the UK. In FR, the College of Veterinary Medicine of Lyon (CNITV) offers 24-hour specialized assistance for suspected cases of animal poisoning and receives between 12,000 and

14,000 calls each year, while the corresponding toxicology laboratory analyses between 1500 and 2000 samples. A second center is located at the College of Veterinary Medicine of Nantes (CAPAE-Ouest) which is open during regular business hours ([Berny, 2007; Berny et al., 2010a](#)). In the UK, the Veterinary Poisons Information Service (VPIS) provides services only to veterinarians, whereas the Royal Society for the Prevention of Cruelty to Animals (RSPCA) records suspected cases of deliberate acts reported by pet owners. In cases where there is hard evidence of pesticide poisoning including sporadic incidents involving livestock and pets, surveillance is conducted by the Veterinary Laboratories Agency (VLA) for production animals and by the Wildlife Incident Investigation Scheme (WIIS) for wildlife.

## SPECIES INVOLVED

In numerous EU countries such as BE, DK, ES, FR, IT, PL, SE and the UK, the species most commonly involved in poisoning incidents is the dog followed by the cat ([Amorena et al., 2004; Giuliano Albo and Nebbia, 2004; DEFRA, 2007; Berny et al., 2010a; Vandenbroucke et al., 2010](#)). With respect to analytical investigations at the CNITV and LTGU laboratories ([Figure 7.1](#)), the resulting numbers are slightly different due to the significant number of wildlife disease surveillance plans, resulting in a substantial number of baits being included in the analyses (22% of cases submitted annually at LTGU).

Among farm animals, most of the poisoning incidents involve cattle (VIDA, 2009; Guitart *et al.*, 2010a; Vandenbroucke *et al.*, 2010) followed by sheep and goats.

The last two are also the most common species involved in poisoning incidents in EL (Roubies *et al.*, 2008; Guitart *et al.*, 2010a). Generally, poultry and pigs are rarely involved in poisoning episodes and minor percentages are also reported for exotic animals and rabbits, often included in the group “other species.”

As far as wildlife, birds, especially waterfowl and raptors, are more commonly reported than mammals as victims of poisoning (Samouris *et al.*, 2007; Guitart *et al.*, 2010b). Apart from specific toxic environmental disasters, deliberate primary or secondary poisoning incidents are of concern in all EU countries and mainly involve birds of prey such as common buzzards and red kites (DEFRA, 2007; Guitart *et al.*, 2010b; Vandenbroucke *et al.*, 2010). Indeed, the proportion of wildlife cases at the CNITV diagnostic laboratory, a part of the national wildlife disease surveillance network (SAGIR), is very high (Berny, 2007). As this network is supported financially by hunters, it mostly deals with game species but an increasing number of cases regarding protected and endangered species has also been recorded (Berny and Gaillet, 2008). A Spanish national program (*Programa Antídoto*) reported several cases of deliberate poisoning of wild birds from 2006 to 2009. During this period, 243 griffon vultures, 42 red kites and 21 Cinereous vultures were found dead, among other wild birds. Official data from the Ministry of the Environment in 2008 indicated that in ES some 7000 members of protected wild species had been poisoned in the previous 15 years.

FIGURE 7.1 Distribution of species (including bait) in poisoning cases at the Belgian Poison Center (BPC calls,  $n = 2,300$  calls annually), the French Animal Poison Control Center (CNITV calls,  $n = 163,883$  from 2000 to 2010), the Belgian Laboratory of Toxicology of the Faculty of Veterinary Medicine from Ghent University (LTGU lab,  $n = 233$  cases annually) and the French College of Veterinary Medicine Diagnostic Toxicology Laboratory in Lyon (CNITV lab,  $n = 16,348$  cases from 2000 to 2010).

**FIGURE 7.2** Toxic classes involved in suspected poisoning cases at the French College of Veterinary Medicine CNITV in Lyon (% in dogs, cats and cattle, from 1991 to 2008).

## TOXIC CLASSES

In most species, pesticides are one of the main causes of poisoning. Statistical data from CNITV confirms this (Figure 7.2), as it is only exceeded by a big group of pollutants (metals, detergents, fertilizers, etc.). Among pets, insecticides, rodenticides, herbicides, fungicides and other pest control substances, used either for plant protection or for indoor pest control, are frequently involved in deliberate or accidental poisoning episodes (Berny *et al.*, 2010a). Drugs are a common source of poisoning for companion animals, caused by the owner's negligence and off-label use of drugs (Modra and Svobodova, 2009; Berny *et al.*, 2010a). Other poisons include household products, plants, fuels, ethylene glycol, zootoxins, cosmetics and drugs of abuse (cocaine or cannabis) (Berny *et al.*, 2010a). For horses, plant poisoning is most frequently reported (Berny *et al.*, 2010a).

In food-producing animals, pesticides are again the most common class of suspected toxicants (Guitart *et al.*, 2010a). In FR, the most common culprits are mainly insecticides and seed-coated products followed by drugs, plants and nutritional disorders resulting from the improper use of foods and feeds and unbalanced diets (e.g., urea poisoning, grain overload). Other common toxicoses involving cattle and pigs result from

plants and metals in ruminants and mycotoxins (Guitart *et al.*, 2010a). In EL, chronic Cu poisoning appears to be a rather common problem mainly in sheep husbandry (Roubies *et al.*, 2008).

For wildlife, pesticides (mainly anticholinesterase and anticoagulant agents) and metals (particularly Pb) are the common causes of poisoning (DEFRA, 2007; Samouris *et al.*, 2007; Mateo, 2009; Modra and Svobodova, 2009; Guitart *et al.*, 2010b). Cyanobacteria toxicoses and botulism involving waterfowl have also been reported (Modra and Svobodova, 2009; Guitart *et al.*, 2010b).

## NON-METALS AND METALLOIDS

Fluorosis in the EU has been observed following the intake of borehole water with high levels of F in region-specific deep-lying clay layers, as reported for example in the case of turkeys (Berny *et al.*, 2010a). A particular incident was reported in BE involving cattle, following the use of calcium sulfate ( $\text{CaSO}_4$ ) as a binder agent in beet pulp resulting in a higher than normal level of F (Vandenbroucke *et al.*, 2010). Poisoning with As predominantly involved cattle, but rarely sheep (Sharpe and

Livesey, 2005; Vandenbroucke *et al.*, 2010). Se toxicoses are also rare but two cases have been reported involving sheep in the UK (Sharpe and Livesey, 2005) and pigs in ES (Casteignau *et al.*, 2006).

## METALS

Telephone calls to EU poison centers, however, do not give us the full picture of animal poisoning. Probably more than any other single toxic agent, certain metals, especially Pb in the case of wild birds, still continue to cause numerous suspected and confirmed animal poisoning cases in the EU.

### Copper

Chronic Cu poisoning is a fairly common clinical problem in the Greek sheep industry (Roubies *et al.*, 2008; Guitart *et al.*, 2010a). Field investigation of one case in EL revealed the source of Cu to be a heap of litter from a broiler farm to which the sheep had accidental access. In the UK, three outbreaks of Cu poisoning which killed at least 55 ewes were detected in 2005 and 2006, associated with organic farming and the consumption of red clover (*Trifolium pratense*) and white clover (*T. repens*). In BE, excessive amounts of Cu in commercially prepared milk replacers caused chronic toxicity in veal calves in two different farms (Vandenbroucke *et al.*, 2010).

### Lead

In a Spanish farmland property located only several meters from a battery-recycling site that had been in operation for 20 years, the death of seven horses and one donkey was documented due to Pb poisoning. Unusual findings have been reported involving horses: a 13-year-old 700 kg Irish Draught cross gelding presenting abnormal respiratory noise during exercise caused by bilateral recurrent laryngeal nerve dysfunction, was diagnosed in the UK subsequent to Pb toxicosis (Allen, 2010).

Pb poisoning is very common for large animals, especially for cattle and sheep. In the UK, more than 450 Pb incidents were investigated by the VLA between 1998 and 2008, mostly related to discarded batteries, old paint and geochemical sources (Payne and Livesey, 2010). In AT, BE, ES and FR, lethal cases involving cattle have also been reported due to the ingestion of fragments of discarded batteries or the contamination of pastures with ash residue from illegal bonfires (Krametter-Froetscher *et al.*, 2007; Guitart *et al.*, 2010a).

In the case of birds, there is extensive literature in the EU documenting poisoning episodes due to the accidental ingestion of small Pb objects, namely spent ammunition and lost fishing weights. This kind of poisoning has long been recognized as a major cause of death in several species (Fisher *et al.*, 2006; Mateo, 2009; Pain *et al.*, 2009). In ES, waterfowl mortality rates were conservatively estimated to be 50,000 a year at the end of the last century, just before the implementation of a ban on the use of Pb shot in the wetlands of this country. Up until 2008, only about half of the EU countries had taken some type of restrictive action against the introduction of Pb through hunting in the marshlands and only four countries (BE, DK, the NL and SE) totally or partially extended this measure to other zones (Thomas and Guitart, 2010). It is worth mentioning that substantial amounts of metallic Pb continue to remain in wetlands, riverine and terrestrial ecosystems for decades or centuries and this represents a source of continued risk of bird poisoning.

The number of hunters and shooters in the entire EU has been estimated to be about 9,000,000 and the Pb ammunition fired yearly about 40,000 t (Thomas and Guitart, 2010). Very high concentrations of Pb shot (>150 per m<sup>2</sup> in the first 10–20 cm of depth) have been reported in some EU wetlands. Consequently a high prevalence of Pb shot ingestion was found, although the intensity varied among bird species and among regions across the EU. Remarkably, Mateo (2009) detected a clear negative relationship between the prevalence of Pb shot ingestion and the wintering population trend in Europe of 15 waterfowl species. Poisoning of swans after ingestion of Pb split-shot or sinkers also occurs in IE and the UK (Perrins *et al.*, 2003). Non-raptor upland birds are also victims and a prevalence of 1.4% and 7.8% for red-legged partridges was found in the UK and ES, respectively.

There have been several reports over the last 10 years of Pb poisoning or high levels of exposure to Pb (compatible with sub-clinical or clinical signs) involving birds of prey (see Table 7.2), both predators and scavengers (Fisher *et al.*, 2006; Mateo *et al.*, 2009; Pain *et al.*, 2009; Guitart *et al.*, 2010b). Raptors are at risk both from prey killed with shotguns, such as wildfowl, upland game birds and rabbits, and with rifles, such as deer and other large game. Recent radiographic studies have shown that many small bullet fragments remain inside prey shot with Pb-based bullets, posing a risk not only for raptors but also for human consumers of this hunted game. Up until 2009, Pb poisoning had been reported in 17 species of birds of prey in Europe, some of which are near-threatened such as the white-tailed eagle or are vulnerable such as the Spanish imperial eagle (Mateo, 2009).

Last but not the least, a case of Pb poisoning involving zoo dolphins was reported in NL in 2008. Apparently, the animals had ingested metal from a damaged diving belt.

TABLE 7.2 Poisonings reported in the last decade in the EU for wildlife species

Species	Poison	Country	Species	Poison	Country
American mink ( <i>Mustela vison</i> )	Pesticides (anticoagulants)	FR	Greylag goose ( <i>Anser anser</i> )	Metals (Pb)	ES
Atlantic puffin ( <i>Fratercula artica</i> )	Oil	ES, FR, PT	Golden eagle ( <i>Aquila chrysaetos</i> )	Metals (Pb)	AT, DE
Barn owl ( <i>Tyto alba</i> )	Metals (Cd)	ES	Griffon vulture ( <i>Gyps fulvus</i> )	Pesticides (anticholinesterases)	ES, EL
Bearded vulture ( <i>Gypaetus barbatus</i> )	Pesticides (anticoagulants)	UK	Herring gull ( <i>Larus argentatus</i> )	Toxins (botulism)	SE
Cinereous vulture ( <i>Aegypius monachus</i> )	Metals (Pb)	ES, FR	Honey bee ( <i>Apis mellifera</i> )	Pesticides	UK
Common buzzard ( <i>Buteo buteo</i> )	Pesticides (strychnine, carbamates)	EL, ES	Marsh harrier ( <i>Circus aureoginosus</i> )	Metals (Hg)	IT
Common guillemot ( <i>Uria aalga</i> )	Metals (Pb)	ES	Mute swan ( <i>Cygnus olor</i> )	Pesticides (carbamates)	CZ
Common kestrel ( <i>Falco tinnunculus</i> )	Oil	ES	Northern gannet ( <i>Sula bassana</i> )	Metals (Pb)	IE, UK
Common raven ( <i>Corvus corax</i> )	Pesticides (carbamates)	BE, CZ	Northern goshawk ( <i>Accipiter gentilis</i> )	Oil	ES, FR, PT
Common scoter ( <i>Melanitta nigra</i> )	Oil	ES, FR, PT	Otter ( <i>Lutra lutra</i> )	Metals (Pb)	DE
Common vole ( <i>Microtus arvalis</i> )	Oil	ES	Peregrine falcon ( <i>Falco peregrinus</i> )	Pesticides (carbamates)	CZ
Common wood pigeon ( <i>Columba palumbus</i> )	Pesticides (carbamates)	CZ	Polecat ( <i>Mustela putorius</i> )	Oil (polycyclic aromatic hydrocarbons)	ES
Dolphin	Pesticides (carbamates)	FR	Razorbill ( <i>Alca torda</i> )	Pesticides (anticoagulants)	FR
Egyptian vulture ( <i>Neophron percnopterus</i> )	Oil	FR	Red kite ( <i>Milvus milvus</i> )	Oil	ES, FR, PT
Eleonora's falcon ( <i>Falco eleonora</i> )	Pesticides (carbamates)	CZ		Metals (Pb)	ES, FR, UK
Eurasian eagle-owl ( <i>Bubo bubo</i> )	Pesticides (carbamates)	FR		Pesticides (anticholinesterases, rodenticides)	FR
European hare ( <i>Lepus europaeus</i> )	Metals (Pb)	NL	Rock pigeon ( <i>Columba livia</i> )	Metals (Pb)	BE
European rabbit ( <i>Oryctolagus cuniculus</i> )	Metals (Pb)	ES	Rough-legged buzzard ( <i>Buteo lagopus</i> )	Pesticides (carbamates)	CZ
Fallow deer ( <i>Dama dama</i> )	Pesticides (carbamates)	ES	Spanish imperial eagle ( <i>Aquila adalberti</i> )	Metals (Pb)	ES
Ferret ( <i>Mustela putorius furo</i> )	Pesticides (anticoagulants)	FR	Waterbirds (several species)	Metals (Pb)	BE, ES, FR, IT, PT
Greater flamingo ( <i>Phoenicopterus ruber</i> )	Pesticides (anticoagulants)	FR		Toxins (cyanobacteria)	ES
	Drugs of abuse (cannabis, hashish)	NL	White-tailed sea eagle ( <i>Haliaeetus albicilla</i> )	Metals (Pb)	AT, DE, FI, SE
	Metals (Pb)	ES, IT		Pesticides (carbamates)	DE, CZ
	Toxins (cyanobacteria)	ES	Wild boar ( <i>Sus scrofa</i> )	Pesticides (carbamates, rodenticides)	CZ, FR

## Other metals and minerals

Mercury (Hg) poisoning is uncommon in domestic animals but should be taken into account as a potential cause of renal failure. In DE, a 4-month-old male German shepherd dog presented with a 2-day history of vomiting, bloody diarrhea and severe renal function impairment. After euthanasia due to the poor prognosis, the owner admitted that a barometer containing Hg had broken in the bedroom about a week before the dog had developed clinical signs. The route of exposure to Hg was presumed to be digestive and respiratory (Hansmann *et al.*, 2009).

In FI, clinical thermometers ranked as one of the top 10 substances involved in dog poisoning inquiries from 2001 to 2003. In IT, Hg exposure following the accidental ingestion of thermometers accounted for more than one third of the total calls regarding metal poisoning in dogs (Giuliano Albo and Nebbia, 2004). Also in IT, a marsh harrier was found dead in a wetland in the north-east and a postmortem diagnosis of Hg poisoning was established, based on levels of  $20\mu\text{g g}^{-1}$  in both liver and kidney.

In NL, an accident took place when a veterinarian advised the owner of a 4.5kg Schipperke dog to give it table salt to induce vomiting after ingestion of one tablet of digoxin. Apparently, the dose administered

was too large and the dog presented neurological signs of salt poisoning and died a few hours later. A similar case occurred in FR with a 5-year-old female Doberman pinscher (Pouzot *et al.*, 2007), but this time it was treated successfully and survived.

Zn toxicity is rarely observed in the EU. Two recent cases involving dogs were reported in the UK when both animals ingested a badly designed tag distributed by an international animal health laboratory to identify that the dogs had been microchipped (Adam *et al.*, 2011). In IT, there was a case of a puppy which died after the ingestion of a pipe fragment from the domestic heating system (Gandini *et al.*, 2002). Unusual clinicopathological findings have also been reported, as in the case of a 6-year-old female Labrador retriever that had ingested a Zn toy; hematological findings revealed a large number of Heinz bodies and marked anemia (Bexfield *et al.*, 2007).

## PESTICIDES

Pesticides are common culprits in animal poisoning cases, as a result of inappropriate or careless use. For companion animals, most of the suspected poisoning cases in BE, EL, ES and FR involved anticholinesterase insecticides mainly carbamates followed by organophosphates (Berny *et al.*, 2010a; Vandenbroucke *et al.*, 2010). In ES, rodenticides are as much to blame as insecticides, whereas in IT the most common cause of pet toxicosis is rodenticides (Berny *et al.*, 2010a). A 6-year retrospective study in AT investigated pesticide poisoning and revealed 123 positive cases; out of 225, 47.2% involved dogs and 34.1% cats (Wang *et al.*, 2007). The highest percentage of incidents was associated with carbamates (50.3%), followed by herbicides and molluscicides (22.3%), anticoagulant rodenticides (18.9%), organophosphates (5.1%) and nonanticoagulant rodenticides (3.4%) (Wang *et al.*, 2007).

Grazing animals are more exposed to pesticides than livestock kept in the barn. Nevertheless, application or storage of pesticides in barns occasionally leads to accidental animal toxicosis. In certain EU countries such as EL and FR, pesticide poisoning is, by far, the most common cause of livestock toxicosis in comparison to other countries such as BE, ES and IT (Guitart *et al.*, 2010a).

Pesticides and more specific anticholinesterase insecticides and rodenticides followed by molluscicides and avicides are among the most frequently reported causes of wildlife poisoning in the EU (Berny *et al.*, 2007; Berny and Gaillet, 2008; SASA, 2000–2009; Guitart *et al.*, 2010b). The investigation of pesticide poisoning of the Cinereous vulture in Spain revealed that carbofuran, aldicarb and

strychnine account for up to 88% of all cases (Hernández and Margalida, 2008). Between 1998 and 2004, 70 animals of the wild fauna (38 birds and 32 mammals) of northern EL were subjected to analysis and 52.63% of birds and 43.75% of mammals tested positive for toxic substances responsible for their death (Samouris *et al.*, 2007). In EL, it appears that anticholinesterase agents are the main cause of wildlife poisoning followed by sporadic incidents due to warfarin and cyanide salts (Samouris *et al.*, 2007; Guitart *et al.*, 2010b).

## Insecticides

Carbamates were found to be responsible for the majority of acute dog poisoning incidents in BE, CZ and IT (Giuliano Albo and Nebbia, 2004; Modra and Svobodova, 2009; Vandenbroucke *et al.*, 2010). Apart from being responsible for 46.9% of positive cases involving sheep and 66.7% involving goats in northern EL (Guitart *et al.*, 2010a), carbamates were also found to be the cause of a recent case involving the poisoning of 55 members of a dairy goat herd following the consumption of drenched carnations at a nearby greenhouse (Giadinis *et al.*, 2009). Moreover, carbofuran has been, by far, the most common cause of wildlife toxicoses in BE and CZ in the last decade (Modra and Svobodova, 2009; Vandenbroucke *et al.*, 2010).

Organochlorine insecticides such as DDT were banned many years ago due to their persistency in the environment and accumulation in the fatty tissues of organisms. However, failure to meet handling regulations of toxic substances and/or waste materials has recently led to cattle poisoning by DDT in CZ (Modra and Svobodova, 2009).

## Rodenticides

The presence of rodenticides and more specific second-generation anticoagulants was analytically confirmed in the majority of suspected companion animal poisoning cases in IT and to a lesser extent in BE, ES and FR (Berny *et al.*, 2010a). Indeed, a study in FR between 2004 and 2007 showed that dogs were involved in cases of anticoagulant poisoning (over 60%) more than other domestic species (Berny *et al.*, 2010b). Similarly, in CZ and AT, anticoagulant rodenticides were recorded as a significant cause of acute poisoning in dogs after deliberate abuse or misuse (Wang *et al.*, 2007; Modra and Svobodova, 2009). Additionally, anticoagulant rodenticides rank among the rare but nevertheless reportable causes of hemorrhage and epistaxis in cats and dogs (Kohn *et al.*, 2003; Mylonakis *et al.*, 2008). Strychnine, although banned in the majority of EU countries, is still reported

as the most common form of rodenticide toxicity in EL, ES, FR and certain regions of IT (Amorena *et al.*, 2004; Berny *et al.*, 2010a).

Hares and rabbits were also found to be significantly present in cases of anticoagulant exposure and account for almost 50% of the submitted cases in FR, followed by scavengers and predators of poisoned rats (Berny *et al.*, 2010b). In the same country, two polecats and an American mink were also reported poisoned by bromadiolone during a screening process aimed at identifying the reason behind the decline in the endangered European mink population (Fournier-Chambrillon *et al.*, 2004). The Predatory Bird Monitoring Scheme (PBMS) and the WIIS in the UK have also identified anticoagulant rodenticides as a common contaminant of wildlife and a cause of mortality (SASA, 2000–2009; DEFRA, 2007).

### Other pesticides

Metaldehyde is usually found in pellets used for molluscicide treatment and that are palatable and easily digested by animals. Dog and cat poisoning by metaldehyde is a big issue in CZ and the UK and has alarmingly increased in other EU countries such as BE, FR and IT where slug pellets are used extensively, not only in farmland but also in home gardens (Modra and Svobodova, 2009; Berny *et al.*, 2010a). Cases of metaldehyde poisoning involving cattle and pigs having access to stored bags of slug pellets have been recorded in the UK (Sharpe and Livesey, 2005).

Occasionally, the herbicide paraquat has been involved in cases of pet poisoning in EL, ES and IT, whereas glyphosate has had minimal impact on companion animal health in FR (Berny *et al.*, 2010a). Other herbicides and fungicides have been infrequently involved in the poisoning of companion animals in the EU.

## OIL

The two most recent oil spills in the EU occurred on the Atlantic coast: the Erika oil spill in December 1999 (FR), and the Prestige oil spill (ES, FR and PT) in November 2002. The Erika oil spill resulted in over 63,000 birds being stranded on beaches, mostly common guillemots (75%), common scoters (4%) and razorbills (4%). Only 6% of them could be released subsequently. The Prestige oil spill involved heavy fuel oil and the total number of birds affected was estimated to be between 115,000 and 230,000, of which only 23,181 could be collected. It was later demonstrated that the Prestige oil spill had a negative effect on the reproductive ability of the local peregrine falcon in Basque Country (Guitart *et al.*, 2010b).

## FEED ASSOCIATED TOXICANTS

As far as companion animals are concerned, feed-related poisoning incidents reported in the last decade involve the accidental intake of chocolate, grapes, raisins, onions, cannabis products and ethanol by dogs (Kammerer *et al.*, 2001; van Wuijckhuise and Cremers, 2003; Sutton *et al.*, 2009; Berny *et al.*, 2010a; Gunning *et al.*, 2010). Dogs may also be prone to the ingestion of theobromine from garden mulch made of cacao bean shells. Ionophores such as lasalocid have been used as an additive in coccidiostatic feed for poultry. Espino *et al.* (2003) described a case of three hunting dogs in ES that developed acute neurological signs associated with lasalocid poisoning after the consumption of several broilers.

Current trends in feed-related livestock poisoning are related to the accidental presence of industrial chemicals/contaminants or to cross-contamination of feed batches with drugs/additives resulting in the exposure of non-target animals. An example of the former is the Belgian dioxin incident in 1999 in which a tank of recycled fats used to produce animal feeds was accidentally contaminated with approximately 100 liters of polychlorinated biphenyl oil. The incident was discovered when poultry poisoning resembling the classic chick edema disease broke out in several farms that had received contaminated feeds (Vandenbroucke *et al.*, 2010). Another example is a melamine contaminated feed crisis in the pig industry in ES. Between 2003 and 2006, 300 to 400 Iberian piglets developed nephrotoxicosis subsequent to exposure to melamine and derivatives. Morbidity was 40–60% and mortality 20–40% in the total population of post-weaning piglets (González *et al.*, 2009).

The phenomenon of cross-contamination is well known where ionophores such as monensin, lasalocid, narasin and salinomycin are concerned. They are frequently used as feed additives and coccidiostats for cattle, sheep and poultry. Acute monensin toxicosis in equids is well documented. Sharpe and Livesey (2005) reported a total of 37 ionophore poisoning incidents in the UK between 1990 and 2002 involving sheep, turkey and poultry. Ionophore poisoning has also been reported in cattle in NL where salinomycin had been accidentally added to the feed powder (Huyben *et al.*, 2001). A special case of acute tiamulin-salinomycin toxicosis in pigs due to a pharmacokinetic interaction between both compounds was reported in BE (Vandenbroucke *et al.*, 2010).

Other feed-related poisoning incidents observed during the last decade in the EU involve well-known toxicants such as nitrate, nitrite and ammonia. Sharpe and Livesey (2005) reported three nitrate poisoning incidents involving cattle and one involving sheep in the UK between 1990 and 2002. Several cases of acute mortality in pigs in BE have been described in which still,

standing water was identified as the nitrite source (Vandenbroucke *et al.*, 2010). In the case of cattle, there have been occasional incidents of overconsumption of soybean meal causing acute carbohydrate fermentation and excessive ammonia release leading to nervous symptoms or of ingestion of cultivated and wild onions (*Allium* spp.) resulting in hemolytic anemia and acute death (Vandenbroucke *et al.*, 2010).

## DRUGS AND RELATED COMPOUNDS

Among the many different therapeutic classes of human drugs, non-steroidal anti-inflammatory drugs (NSAIDs), benzodiazepines and barbiturates are the most common contributors to animal poisoning (Berny *et al.*, 2010a). While in the USA several studies dealing with the ingestion of the non-benzodiazepine hypnotic drug zolpidem by dogs have been reported, only one case of cat poisoning has been published in PL in the EU (Czopowicz *et al.*, 2010). In addition, the ingestion of calcipotriol ointment (a structural analog of calcitriol) by a dog was reported in the UK (Torley *et al.*, 2002). In the same EU country, ingestion of hydroxycarbamide (hydroxyurea) tablets by a dog was associated with methemoglobinemia (Wray, 2008). Another well-known accidental ingestion of drugs involves the intake of equine de-worming medication by dogs. Collies are especially known for their breed-dependent adverse reaction to ivermectin (Berny *et al.*, 2010a).

Livestock poisoning cases related to human and veterinary drugs has seldom been reported in the EU in the last decade. Cases include the poisoning of pigs by vitamin D<sub>3</sub> in DE due to the erroneous presence of the vitamin in ready-to-use food mixes (Heinritzi *et al.*, 2000), calves by doxycycline in BE after receiving high doses as treatment for respiratory disorders (Vandenbroucke *et al.*, 2010) and sheep and cattle in the UK due to the misuse of unlabeled or out-of-date diazinon products (Sharpe *et al.*, 2006).

## HOUSEHOLD PRODUCTS

Since dogs and cats share our domestic environment, they are highly exposed to household products (e.g., 720 cases in FR in 2003) (Berny *et al.*, 2010a). Among them, hydrocarbons account for nearly 40% of poisoning incidents, especially in the case of cats exposed to domestic fuel, xylene and other common solvents used in paint and paint solvents. Exposure to these substances usually results in very severe cases with a high mortality rate.

Other common household toxicants include detergents and caustics (bleach, strong acids and bases), accounting for almost 40% of the 720 cases. In 2004, 69 calls related to fertilizer poisoning were registered in FR and most of them (65%) resulted in moderately severe cases with digestive disorders. Similarly in IT, bleach and detergents are often involved in the poisoning of both cats and dogs, whereas petroleum distillate poisoning was reported mainly in cats (Amorena *et al.*, 2004; Giuliano Albo and Nebbia, 2004). In IT and ES, ethylene glycol poisoning involving dogs has been recorded (Berny *et al.*, 2010a) and some recent cases involving cats have been analytically confirmed in Catalonia. Long-term exposure and poisoning of a dog by ethylene glycol has also been reported, eventually leading to renal failure (Goicoa *et al.*, 2003).

## TOXINS

Suspected toxin poisoning has been reported in the case of companion animals (phytotoxins and zootoxins), food producing animals (phytotoxins and mycotoxins) and wild birds (botulism and cyanobacteria).

### Plants

Poisoning or suspected poisoning of companion animals as a result of ingestion of plants is a relatively common occurrence and cats appear to be more sensitive and more at risk than dogs, presumably because they tend to chew on plant leaves (Berny *et al.*, 2010a). Often the cases are related to accidental ingestion of ornamental plants rather than wild plants, particularly at certain times of the year. Cats are generally more likely to be poisoned by household/ornamental plants and dogs are more at risk from wild plants (Giuliano Albo and Nebbia, 2004; Berny *et al.*, 2010a).

Liliaceae and Araceae are the two major plant species involved in poisoning of companion animals in FR; oleander (*Nerium oleander*), castor bean (*Ricinus communis*) and Jimson weed (*Datura stramonium*) cases are also frequently observed (Berny *et al.*, 2010a).

In IT, many ornamental plants lead to dog poisoning such as dumbcane (*Dieffenbachia* spp.), ficus (*Ficus benjamina*), pittosporo (*Pittosporum tobira*), poinsettia (*Euphorbia pulcherrima*), rhododendron (*Rhododendrum hirsutum*), tiger lily (*Lilium tigrinum*) and jessamine (*Jasminum officinalis*) (Amorena *et al.*, 2004; Giuliano Albo and Nebbia, 2004; Berny *et al.*, 2010a). In BE and CZ, black locust (*Robinia pseudoacacia*), tansy ragwort (*Senecio jacobaea*) and oleander have been responsible for

horse poisoning outbreaks (Modra and Svobodova, 2009; Berny *et al.*, 2010a; Vandenbroucke *et al.*, 2010). In addition, horse poisoning resulting from European yew tree (*Taxus baccata*) exposure is very common in BE and FR (Berny *et al.*, 2010a; Vandenbroucke *et al.*, 2010).

Although livestock poisoning by toxic plants is frequent, these cases often remain only suspected, unconfirmed by analytical diagnoses. Livestock are commonly poisoned by bracken fern (*Pteridium aquilinum*), European yew tree, oak trees (*Quercus* spp.) and ragwort (*Senecio* spp.) in many EU countries (Guitart *et al.*, 2010a; Vandenbroucke *et al.*, 2010; VPIS, 2010).

## Other toxins

In the EU, a number of different avian species have been involved in outbreaks of botulism and the species most affected by this was aquatic birds (Guitart *et al.*, 2010b). Botulism outbreaks in poultry, sheep and cattle are fairly common too (Sharpe and Livesey, 2005; Modra and Svobodova, 2009). Cyanobacteria toxic blooms are the cause of mass mortality of wild birds in inland water systems worldwide and two recent episodes have been reported in ES in the Doñana National Park (López-Rodas *et al.*, 2008; Guitart *et al.*, 2010b).

Although mycotoxicoses are commonly suspected, published reports of poisoning are scarce. Episodes involving different species like cattle, pigs, poultry and sheep have been recently reported in BE, CZ, ES, FR, IT, PL and the UK (Sharpe and Livesey, 2005; Modra and Svobodova, 2009; Obremsky and Zielonka, 2009; Guitart *et al.*, 2010a; Moyano *et al.*, 2010; Vandenbroucke *et al.*, 2010).

Reported cases due to venomous bites by viper (*Vipera* spp.), common toad (*Bufo bufo*) and pine caterpillar (*Thaumetopoea pityocampa*) mostly involve dogs (Amorena *et al.*, 2004; Giuliano Albo and Nebbia, 2004; Berny *et al.*, 2010; Lervick *et al.*, 2010).

## CONCLUSIONS

European toxicoepidemiological data demonstrate that pesticides are the most common class of toxicants in all species. Poisoning in companion animals is a frequent problem and dogs are the most commonly poisoned species, followed by cats and horses. In food-producing animals information on poisoning is limited and fragmented and occurs predominantly in cattle followed by sheep and goats. A small percentage of cases is also reported for poultry and pigs. Poisoning episodes in wildlife are widespread and present a major

investigational problem for toxicology and forensic laboratories. Knowledge of the common features of animal poisoning is central to any endeavor to reduce mortality and it is therefore essential that coordinated and integrated efforts are made between European countries for sharing information.

# Chemicals of terrorism

Tina Wismer

## INTRODUCTION

Chemical agents may be chosen by terrorists as they can be dispersed over large areas and can eventually penetrate even the most well-defended positions. These agents can be deployed against specific targets, and depending on the agent used, the effects can be immediate or delayed. Chemical agents can cause incapacitation, disorientation or death. Many of the more commonly used agents can be produced inexpensively and easily stored.

There are four basic types of military agents that can be used for chemical terrorism: choking agents (chlorine, phosgene), blister agents (mustard, Lewisite, phosgene oxime), blood agents (cyanide, hydrogen cyanide) and nerve agents (tabun, sarin, soman, VX). Chemical warfare agents can be delivered by a variety of methods: bomb, spray tanks; rockets; missiles; land mines; and artillery projectiles (USACHPPM, 2001a). Few indicators of a chemical attack may be evident at first. The initial observation of unusual signs and symptoms that correlate with nerve, vesicant, blood or pulmonary agent exposures should raise immediate suspicion of poisoning.

The history of chemical warfare dates back to the beginning of the last century. The first chemical warfare agent of modern times was chlorine. It was used by the German army at Ypres in 1915 against the Allies. Experiencing some success, the Germans then began to mix chlorine with phosgene, or deployed phosgene alone as a weapon. Phosgene, arsenicals, blister agents and mustard gas were estimated to be responsible for approximately 1.3 million casualties during the war,

including at least 90,000 fatalities (Raffle *et al.*, 1994; Bingham *et al.*, 2001; HSDB, 2005). Phosgene accounted for 80% of all gas deaths.

Chemical warfare agents do not need to be lethal to be disruptive. Although the mortality rate was not as high as with phosgene, mustard gas was the number one cause of casualties in WWI (Raffle *et al.*, 1994). Mustard gas caused severe injuries, and due to its persistence, remained a hazard and barrier to troop movements.

Chemical weapons have been used in a few recent civil wars. Phosgene was used by Egyptian bombers against Yemeni royalist forces in the Yemeni civil war in the 1980s (Evison *et al.*, 2002). The Iraqi military used both mustard gas and HCN against the Kurds leading to as many as 3000 deaths (Somani and Babu, 1989). Iraq also used "Yellow rain" (a mixture of mycotoxins, mustard gas and nerve agents) against Iran in 1984. Approximately 100,000 unprotected soldiers suffered severe and long-lasting injuries. The fatality rate was 20% (Drasch *et al.*, 1987).

With the changing political climate around the world, several terrorist groups have used chemical warfare to bring attention to themselves and further their cause. Aum Shinrikyo (Supreme Truth) has used several chemical attacks recently to promote their agenda. In June 1994, they attempted to assassinate three Japanese judges by releasing sarin gas in the community where they lived. Aum Shinrikyo had modified a truck with a special device to release the sarin gas. Seven people, but not the judges, died and 280 were injured. Emboldened by this partial success, on March 20, 1995, Aum Shinrikyo carried out a sarin gas attack on the Tokyo subway. The terrorists used sharpened umbrellas to puncture lunch boxes and bags filled with dilute sarin.

Eleven people died and more than 5500 were injured (Kaplan and Marshall, 1996). On April 20, 1995, Aum Shinrikyo changed their chemical agent and released phosgene gas in a Yokohama train station, causing injuries to 300 people.

Chemical agents also have their problems as agents of terror. They are most effective in confined spaces. Chemical warfare agents dissipate quickly and degrade or adhere to surfaces. Attacks need to be well coordinated for dispersal of the agent and escape from the area of deployment.

Both livestock and pet animals can be exposed to chemical agents during a terrorist attack. Treatment of animals is secondary to treating human casualties. Humane euthanasia may be the only recourse due to financial or logistical concerns.

## CHLORINE GAS

### Background

Chlorine (Agent CL,  $\text{Cl}_2$ ) has been used as a choking or pulmonary agent for military purposes under the name bertholite (Budavari, 2000). It is a greenish-yellow diatomic gas with an irritating, pungent, or suffocating odor (Lewis, 1997; Budavari, 2000; NIOSH, 2007). Chlorine gas is heavier than air and will settle in low areas.

### Pharmacokinetics/toxicokinetics

The initial effects of chlorine gas exposure can appear very rapidly, depending upon the concentration. Due to chlorine's water solubility and chemical reactivity, it can have a greater effect on the lower respiratory tract as a large percentage bypasses the upper airways. Respiratory, dermal and ocular irritation starts immediately and acute lung injury peaks in 12 to 24 hours.

### Mechanism of action

Chlorine gas is a strong irritant, and in concentrated amounts may be corrosive to mucous membranes when inhaled or ingested. When chlorine combines with tissue water it produces hydrochloric acid and reactive oxygen species. These free radicals are potent oxidizers, causing further tissue damage. The damage to the respiratory epithelium leads to alveolar capillary congestion followed by high fibrinogen edematous fluid (Noe, 1963). Hypoxemia results from development of atelectasis,

emphysema and membrane formation. Death usually occurs within 48 hours from cardiac arrest secondary to hypoxia (Decker, 1988).

### Toxicity

Inhalation is the main route of chlorine gas exposure. Chlorine gas is very irritating on contact and can be caustic to the eyes, skin, nose, throat and mucous membranes. Ocular exposure can result in severe or permanent eye injury. Dermal exposure may cause erythema, pain and irritation. Both liquid chlorine and high concentrations of gaseous chlorine can cause dermal burns (Raffle *et al.*, 1994). Signs of exposure to chlorine gas include: rhinorrhea, ataxia, syncope, muscle weakness, dermatitis, dyspnea, tachypnea, pneumonia, bronchospasm and acute lung injury. High concentrations may cause laryngospasm, cardiovascular collapse, tachycardia and respiratory arrest (Noe, 1963). Respiratory symptoms may be immediate or delayed up to several hours depending on the concentration (Bingham *et al.*, 2001). Hypoxia is common and death may be rapid. See Table 8.1 for severity of signs expected after inhalation at certain ppm concentrations of chlorine gas.

Symptoms generally disappear within six hours after mild exposures, but may continue for more than 24 hours with severe exposures. Moderate to severe exposures can result in chronic respiratory dysfunction (Decker, 1988; Schwartz *et al.*, 1990).

Chlorine is both teratogenic and carcinogenic. Chlorine at 100 ppm when given to pregnant rats in their water caused both biochemical and metabolic effects in

TABLE 8.1 Different effects of exposure levels of chlorine gas

Values in ppm	Effect
0.2–3.5	Odor detection (some tolerance develops)
1–3	Mild mucous membrane irritation that can be tolerated for up to 1 h
3	Extremely irritating to the eyes and respiratory tract
5	Severe irritation of eyes, nose, and respiratory tract; intolerable after a few minutes
14–21	Immediate irritation of the throat; dangerous if exposed for 30–60 min
15	Irritation of the throat
30	Moderate irritation of the upper respiratory tract; immediate chest pain, vomiting, dyspnea, cough
35–50	Lethal in 60–90 min
40–60	Toxic pneumonitis and acute lung injury; dangerous for even short periods
430	Lethal over 30 min
1000	Fatal within a few minutes

Lewis (2000), HSDB (2005) and Bingham *et al.* (2001).

the newborns (RTECS, 2006). Carcinogenicity has only been demonstrated in chronic exposures (Morris *et al.*, 1992; RTECS, 2006).

## Treatment

Move animals into fresh air and monitor for respiratory distress. If coughing or dyspnea develops, evaluate for hypoxia, acidosis, respiratory tract irritation, bronchitis or pneumonitis. Oxygen supplementation along with intubation and ventilation may be needed. Beta adrenergic agonists can help if bronchospasm develops (Guloglu *et al.*, 2002).

Flush eyes with copious amounts of room temperature 0.9% saline or water for at least 15 minutes. Fluorescein staining should be performed to check for corneal defects (Grant and Schuman, 1993). Animals should be bathed with copious amounts of soap and water. Chlorine blood concentrations are not clinically useful as it converts directly to hydrochloric acid in the lungs and other tissues.

Animal models have suggested that corticosteroids can hasten recovery from severe chlorine gas poisoning (Traub *et al.*, 2002); however, administration of steroids to exposed humans has not been shown to provide any significant change (Chester *et al.*, 1977). Pigs exposed to chlorine gas responded best to a combination of aerosolized terbutaline and budesonide than to either therapy alone (Wang *et al.*, 2004). Sheep exposed to chlorine gas and then nebulized with 4% sodium bicarbonate had decreased mortality and improved arterial blood gas values (Chisholm *et al.*, 1989).

## Concluding remarks

Rescuers should wear self-contained breathing apparatus (SCBA) and have protective clothing when entering contaminated areas. Chlorine dissipates quickly in warm climates and does not leave an environmental residue (Munro *et al.*, 1999). The potential for secondary contamination is low, as the gas is not carried on contaminated clothing.

# PHOSGENE

## Background

Phosgene (Agent CG, carbonyl chloride,  $\text{CCl}_2\text{O}$ ) is classified as a choking agent. It is a colorless, non-combustible and highly toxic gas. At room temperature phosgene is

easily liquefied (ACGIH, 2005; CHRIS, 2005; Proctor and Hughes, 2004; NIOSH, 2007) and at high concentrations, the gas has an odor described as strong, suffocating and pungent. Lower concentrations are described as smelling like green corn or "haylike" (Raffle *et al.*, 1994; Budavari, 2000; Pohanish, 2002). Phosgene will sink in water (Budavari, 2000; Bingham *et al.*, 2001).

## Pharmacokinetics/toxicokinetics

Dyspnea develops 2 to 6 hours post exposure in most patients, but may be delayed up to 15 hours (Borak and Diller, 2001). With high concentrations ( $>200$  ppm), phosgene can cross the blood-air barrier in the lung and cause hemolysis and coagulopathies (Sciuto *et al.*, 2001).

## Mechanism of action

Phosgene is a lower respiratory tract irritant. Due to its low water solubility and low irritancy of the upper respiratory system, phosgene is able to penetrate deeply into the lungs (Franch and Hatch, 1986). Phosgene gas interacts with water in the lungs, where it is hydrolyzed into hydrochloric acid leading to cellular injury (Murdoch, 1993). Phosgene also acylates sulfhydryl, amine and hydroxyl groups (Borak and Diller, 2001). This results in protein and lipid denaturation, changes in membrane structure and disruption of enzymes. Phosgene increases pulmonary vascular permeability, leading to increased fluid accumulation in the lung interstitium and alveolae. This fluid accumulation results in gas diffusion abnormalities and pulmonary edema (Diller, 1985; Ghio *et al.*, 1991). Phosgene also decreases energy metabolism and disrupts the glutathione redox cycle. Animals exposed to phosgene have elevated levels of leukotrienes and neutrophil chemotactic agents. Neutrophils congregate in the lung releasing cytokines and other reactive mediators which contribute to pulmonary injury (Ghio *et al.*, 1991; Sciuto *et al.*, 1995). Bronchiolar epithelium is damaged, resulting in local emphysema and partial atelectasis. Death is due to anoxia secondary to pulmonary edema.

## Toxicity

Most exposures to phosgene are from inhalation. The odor of phosgene gas is not sufficient to warn individuals of toxic levels and with high concentrations, olfactory fatigue can occur (Borak and Diller, 2001; ACGIH, 2005). The degree of pulmonary injury relates to the concentration and length of exposure (Bingham *et al.*, 2001) and

initial symptoms are not considered to be a good indicator of prognosis (Diller, 1985).

Exposure to concentrations less than 3 ppm may not be immediately accompanied by symptoms, but delayed effects usually occur within 24 h of exposure. Concentrations as low as 3 to 5 ppm can cause immediate conjunctivitis, rhinitis, pharyngitis, bronchitis, lacrimation, blepharospasm and upper respiratory tract irritation and extended (170 minutes) exposure was fatal (Diller, 1985; Wells, 1985; Proctor and Hughes, 2004). A dose of 50 ppm for 5 minutes may cause pulmonary edema and rapid death (Chemstar, 1996; Borak and Diller, 2001; RTECS, 2006).

A lag time of 1 to 6 h before the onset of respiratory distress and pulmonary edema is common with acute, high-dose exposures ( $>50$  ppm/min). Signs can be delayed for up to 24 (most common) or 72 h with exposures to lower concentrations (Proctor and Hughes, 2004; Pohanish, 2002). Thoracic radiographs can show evidence of pulmonary edema within 1 to 2 h of high-dose exposure, 4 to 6 h after moderate exposure and approximately 8 to 24 h after low-dose exposure (Diller, 1985).

Progressive dyspnea, productive cough, cyanosis and hemoptysis are common initial signs following exposure (Wells, 1985; Borak and Diller, 2001). Hypoxemia and hypoventilation are common secondary to respiratory distress (Wells, 1985). Animals may develop secondary GI, hepatic, renal or brain injury, due to lack of oxygenation. In a dog model, severe phosgene poisoning caused initial bradycardia followed by tachycardia and progressive hypotension (Patt *et al.*, 1946). Cardiac failure may occur secondary to severe pulmonary edema.

Direct contact with the liquefied material can cause dermal burns (Proctor and Hughes, 2004) and severe eye irritation, corneal opacification and frostbite (Proctor and Hughes, 2004). Corneal opacification has also been produced in cats exposed to highly concentrated phosgene gas (Grant and Schumann, 1993).

Prognosis is directly related to the extent of pulmonary injury. If the animal survives 24 to 48 hours, the prognosis improves. Pulmonary edema begins to resolve after 2 to 3 days. Survivors may have suppressed natural killer cell activity and are more susceptible to infectious agents. Secondary infections may become evident 3 to 5 days after exposure. They may also have persistent exertional dyspnea, reduced exercise capacity and abnormal pulmonary function tests (Borak and Diller, 2001).

## Treatment

If inhalation exposure occurs, remove animals to fresh air (higher ground) and monitor for respiratory distress. Exposed skin should be washed with soap and water. Exposed eyes should be flushed for 15 minutes with

tepid water. Asymptomatic animals should be monitored for 12–24 hours for development of pulmonary edema (Borak and Diller, 2001). Symptomatic animals should receive 100% oxygen. If arterial blood gases or  $pO_2$  continues to fall, intubation and ventilation is recommended. Plasma phosgene levels are not clinically useful and there is no specific antidotal agent. Management of patients with pulmonary edema from phosgene is the same as for an ARDS (acute respiratory distress syndrome) patient. Diuretics are not indicated and can worsen volume depletion. Mechanical ventilation with oxygen and PEEP (positive end-expiratory pressure) is the mainstay of treatment.

Intravenous fluids can help with cardiovascular support, but monitor closely for signs of volume overload. Colloids are preferred as they will remain in the vascular space for a longer period of time. Most arrhythmias will resolve with adequate oxygenation.

Nebulized beta adrenergic agonists are recommended if bronchospasm occurs. In a rabbit inhalation study, animals exposed to toxic levels of phosgene were dosed with intravenous aminophylline and subcutaneous terbutaline. If given within 10 minutes post exposure, it prevented noncardiogenic pulmonary edema (Kennedy *et al.*, 1989). N-acetylcysteine (Mucomyst<sup>®</sup>) administered intratracheally to rabbits 45 to 60 min after inhalational exposure to phosgene (1500 ppm/min) decreased pulmonary edema, production of leukotrienes, lipid peroxidation and maintained normal glutathione levels as compared to rabbits exposed to phosgene only (Sciuto *et al.*, 1995). Ibuprofen was shown to protect against acute lung injury from phosgene in rats and rabbits (Guo *et al.*, 1990). Supplemental oxygen and sodium bicarbonate were beneficial in dog experiments (Mautone *et al.*, 1985). Aerosolized surfactant improved lung compliance in a dog model, but the effects of the surfactant on the development or resolution of pulmonary edema were not determined (Mautone *et al.*, 1985). Animal experiments also suggest that corticosteroids, prostaglandin E1 and atropine may be helpful in treating phosgene-induced pulmonary edema (Chemstar, 1996).

## Concluding remarks

Phosgene is heavier than air and will pool in low-lying areas. This heavy vapor density, 3.4 times that of air, made phosgene practical for trench warfare. Phosgene is considered to be nonpersistent in the environment. Air concentrations are reduced by atmospheric water, such as rain or fog (Borak and Diller, 2001). Rescuers should wear proper protective clothing when treating exposed patients. Fortunately, the potential for secondary contamination of rescue personnel is low, as the gas does not persist in fabric or leather. Phosgene is used extensively

in industry as a chemical precursor and this widespread availability makes it an attractive agent for terrorist use.

## MUSTARD GAS

### Background

Mustard gas (Agent H,  $C_4H_8Cl_2S$ ) is a vesicant agent used in chemical warfare. It causes necrosis of the skin, eyes and respiratory tract. It is an organic lipophilic sulfide which is a bifunctional alkylating agent (Borak and Sidell, 1992; Lewis, 1997). Mustard agent is a clear oily liquid in its pure state. Due to impurities, however, it is normally amber to black, or yellow to brown in color (Munro *et al.*, 1999; USACHPPM, 2001b; HSDB, 2005). The liquid becomes aerosolized when dispersed by spraying or by explosive blast from a shell or bomb (USACHPPM, 2001a). Mustard gas has an odor resembling garlic, mustard or horseradish. Systemic poisoning occurs more easily in warm climates than in temperate ones. Mustard gas is still considered a major threat by the U.S. military, as it is easily manufactured and is both incapacitating and lethal.

### Pharmacokinetics/toxicokinetics

Mustard gas is toxic by all routes of exposure (oral, inhaled, dermal and ocular) (EPA, 1985a; Sidell *et al.*, 1997; Lewis, 2000; Pohanish, 2002). Skin penetration of both the liquid and vapor is rapid, and mustard causes both localized cellular and systemic damage (NATO, 1973). Mustard penetrates down hair follicles and sweat glands within minutes. Dermal absorption of mustard varies by species. About 20% of a dermal dose is absorbed through human skin, while up to 75% is absorbed through the skin in rats (Hambrook *et al.*, 1992; Smith, 1999). Ocular absorption also happens within minutes. The latent period for absorption is inversely related to the dose, temperature and humidity (NATO, 1973). Lesions develop within 2 to 3 hours with high-level exposures, and 8 to 10 hours after milder exposures (Requena *et al.*, 1988).

The chemical reaction with biological tissue occurs rapidly but symptoms are typically delayed by several hours (Grant and Schuman, 1993; Sidell *et al.*, 1997). Dog studies show that equilibrium between blood and tissues was achieved within 5 minutes after inhalation (IARC, 1975). Once inside the body, mustard accumulates (in descending order) in fat, skin with subcutaneous fatty tissue, brain, kidney, muscle, liver, cerebrospinal fluid, spleen and lung (Drasch *et al.*, 1987; Somani and Babu,

1989). There are no measurable levels of mustard in the liquid from a skin blister. Urine is the major route of excretion in rabbits, mice and rats. After IV administration in rats and mice, the majority is excreted in 72 to 96 hours (Maisonneuve *et al.*, 1993; Dacre and Goldman, 1996). Only about 6% is eliminated in the feces (IARC, 1975). Bone marrow damage is not evident for 3 to 5 days post exposure. Leukopenia usually occurs at day 7 to 10 following exposures (Garigan, 1996).

### Mechanism of action

The mechanism of action for cellular damage by mustard is unknown, but four theories have been proposed: alkylation of deoxyribonucleic acid, oxidative stress upon cell components, depletion of glutathione, and an inflammatory response (Smith *et al.*, 1995). Mustard gas is a bifunctional alkylating agent. It forms covalent cross-links between the double strands of DNA which inhibits DNA synthesis. Mustard-induced blistering appears to be correlated to DNA damage in the basal cells (Andreassi, 1991; Cowan *et al.*, 1998). Mustard penetrates the skin and damages the cells separating the epidermis from the dermis. Mustard disrupts the hemidesmosomes leading to blister formation between the two layers (Sidell *et al.*, 1997). Skin biopsies from mustard gas blisters revealed a separation of the basal cells from one another and the development of multinucleated cells (Bismuth *et al.*, 1995).

Mustard also causes oxidative stress on intracellular molecules. Mustard forms an electrophilic ethylene episulfonium intermediate in the aqueous of the cytosol (Smith, 1999). The episulfonium ion reacts with sulfhydryl groups leading to increased intracellular calcium. The increased calcium level breaks down the microfilaments needed to maintain cell integrity and induces apoptosis by activating endonucleases, proteases and phospholipases (Smith *et al.*, 1995). Mustard gas may also exert its toxicity via depletion of glutathione. Without glutathione, reactive oxygen species react with membrane phospholipids causing loss of membrane function, fluidity and integrity. Inflammation and sulfur mustard-increased proteolytic activity are also implicated in contributing to mustard pathology (Cowan *et al.*, 1998).

### Toxicity

Mustard gas is a radiomimetic as it produces lesions similar to radiation (Andreassi, 1991; Sidell *et al.*, 1997). Tissues with high cell turnover are the most affected. Being a vesicant, mustard gas can produce erythema, severe pruritus, blistering, ulceration and necrosis of

exposed skin (Borak and Sidell, 1992; ITI, 1995; Dacre and Goldman, 1996; Budavari, 2000; Pohanish, 2002). With dermal exposure, the skin initially appears pale and then becomes erythematous within a few hours of exposure (Requena *et al.*, 1988). Blistering usually starts on the second day and progresses for several more days. Erythema disappears in 3–7 days, while the ulcers take 6–8 weeks to heal (Garigan, 1996; Sidell *et al.*, 1997). Brown or black hyperpigmentation usually occurs after resolution of the burns, especially in areas with thinner skin. Skin involvement is most severe at warm and moist sites (genitalia, perineal regions, groin, skin folds and axillae). This is due to the high number of sweat glands in these areas. The smallest reported blister-causing dose on the skin is 0.02 mg of mustard (Smith *et al.*, 1995).

The eyes are very sensitive to the effects of mustard gas (NATO, 1973; Borak and Sidell, 1992; Dacre and Goldman, 1996). Pain, lacrimation, corneal ulceration, along with photophobia, swelling, blepharospasm and blindness can be seen (Garigan, 1996). Conjunctivitis appears early, developing 4 to 6 hours after exposure. Eye lesions have been reported at a Ct (concentration  $\times$  time) of 10 mg-min/m<sup>3</sup> (Sidell *et al.*, 1997). Porcelain-white areas in the episcleral tissues adjacent to the cornea and formation of large, tortuous, sausage-shaped varicose veins are pathognomonic signs of mustard gas poisoning (Grant and Schuman, 1993). Chronic conjunctivitis and keratopathy has been reported in people (Blodi, 1971).

The main non-dermal toxic effects are on the respiratory tract. Irritation or ulceration of the respiratory tract can occur (Vogt *et al.*, 1984; Borak and Sidell, 1992; Dacre and Goldman, 1996; ITI, 1995; Budavari, 2000). Cough, dyspnea and pulmonary edema may occur up to 24 hours after inhalation. One ppm in air is a lethal concentration for dogs and 0.650 ppm mustard results in a 33% mortality rate in rabbits (OHM/TADS, 2005). See Table 8.2 for LD<sub>50</sub> information in various species by multiple routes of exposure. Mild pulmonary exposures produce rhinorrhea, sneezing, epistaxis and cough within 12–24 hours of exposure. Large exposures can cause pulmonary damage. In severe cases, hypoxia and respiratory acidosis are seen. Seizures appear to occur only following extremely high acute doses (Sidell *et al.*, 1997).

Leukopenia, thrombocytopenia, pancytopenia and anemia have all been reported due to depressed myelopoiesis from destruction of precursor cells in the bone marrow (Vogt *et al.*, 1984; Borak and Sidell, 1992; Dacre and Goldman, 1996). Bone marrow aplasia can be seen in severe cases. Secondary to bone marrow damage, overwhelming infection can result in death (Sidell *et al.*, 1997).

Mustard gas is a possible human and animal teratogen. It has been linked to an increased incidence of cleft lip and cleft palate in Iranian children born during

Lewis (2000) and RTECS (2006).

the Iran–Iraq war (Taher, 1992). Abnormalities of the musculoskeletal system were observed in the offspring of rats orally dosed with mustard gas, but such effects may only occur at doses high enough to be toxic to the dams (Dacre and Goldman, 1996; RTECS, 2006). Other rat and rabbit studies showed no correlation (Hackett *et al.*, 1987). Mustard gas is considered both carcinogenic and neoplastic. Mustard gas has caused carcinomas in the skin, appendages, lungs, thorax and blood (leukemia) of rats and mice via both inhalation and IV exposure (RTECS, 2006).

## Treatment

Move animal into fresh air. Do not induce emesis. Activated charcoal administration after oral ingestion is controversial. It appears to have some beneficial effects if administered within one hour of ingestion. Sodium thiosulfate has been used as a “mustard scavenger” and giving 2% sodium thiosulfate solution orally may help in cases with ingestion exposures (Borak and Sidell, 1992; Dacre and Goldman, 1996). If signs or symptoms of esophageal burns are present, consider endoscopy to determine the extent of injury. Perforation and stricture formation could result.

Flush eyes with tepid water for at least 15 minutes. After flushing, instill 2.5% sodium thiosulfate to help neutralize the mustard. Time to decontamination is very important with ocular exposures. Mustard droplets disappear from the eye very quickly, and late flushing of the eye generally provides no benefit (Sidell *et al.*, 1997). Topical antibiotics and mydriatics should be used if corneal lesions are present. Corneal transplants have been performed on some human patients with good results and may be considered for some valuable animals (Blodi, 1971).

Several general dermal decontamination methods can help reduce the toxicity of mustard gas. Bathe animals with copious amounts of soap and water. Dermal decontamination needs to be implemented quickly, as once mustard has reacted with the skin, it cannot be easily removed (Sidell *et al.*, 1997). A 2.5% sodium thiosulfate

solution has been used to neutralize dermal mustard exposures (Garigan, 1996). Dilute (0.5%) hypochlorite solutions may also be used for skin decontamination (Borak and Sidell, 1992). Clays, such as Mineral Cationic Carrier (MCC®: Kodona; Zagreb, Croatia), a synthetic zeolite, have shown efficacy in dermal decontamination with mustard gas exposures (Vucemilovic *et al.*, 2008). Monitor for dermal effects, which are delayed and progressive. Dermal lesions behave like a chemical burn or radiomimetic effect. Topical silver sulfadiazine should be applied to all affected areas. In a mouse model, topically applied dexamethasone and diclofenac reduced inflammatory parameters when applied within 4 hours (Dachir *et al.*, 2004). Healing can take weeks to months and infection is common (Borak and Sidell, 1992). Removal and debridement of closed blisters is controversial. Blisters should be left intact until they rupture spontaneously or unless they are extremely large or inhibit motion (Roberts, 1988). Tetanus toxoid should be given to all equine and ovine patients. Tetanus prophylaxis of other species should be determined on a case-to-case basis.

Monitor for coughing and respiratory distress. If respiratory abnormalities occur, monitor arterial blood gases and/or pulse oximetry, and thoracic radiographs. Thoracic radiographs may show an infiltrate within the first two days (Smith, 1999). Nebulization of 2.5% sodium thiosulfate may help neutralize the mustard gas. N-acetylcysteine (Mucomyst®) is also a potential mustard gas antagonist (Garigan, 1996). A loading dose of 140mg/kg should be given, followed by 40mg/kg every 4 hours for a total of 17 doses (Garigan, 1996). Administer oxygen and inhaled beta agonists if needed. Intubation and ventilation may be needed. Melatonin can be beneficial in acute mustard toxicosis. It is a scavenger of both oxygen- and nitrogen-based free radicals and regulates gene expression of antioxidant enzymes (e.g., SOD, GSH-Px) (Reyes-Toso *et al.*, 2004; Tan *et al.*, 2007). Melatonin also decreases inflammation by blocking pro-inflammatory cytokines and sparing ATP production (Tan *et al.*, 2007). Combinations of parenteral dexamethasone, promethazine, vitamin E and heparin have shown protective effects against mustard gas poisoning in laboratory animals (Vojvodic *et al.*, 1985; Requena *et al.*, 1988).

Monitor CBC with platelets for 2 weeks after exposure. Leukopenia develops at 7 to 10 days following a severe acute exposure (Garigan, 1996). Prophylactic antibiotics are not recommended, but a broad spectrum antibiotic should be started if leukopenia develops (Sidell *et al.*, 1997). Antibiotic choice should be based on culture and sensitivity if possible.

Mustard can be detected in air, urine and body tissues using different methods. Mustard gas or its thiodiglycol metabolite can be detected in urine up to a week after

acute exposure using gas chromatography-mass spectrometry (Vycudilik, 1985). Other than for confirming the diagnosis, measuring mustard gas levels is not likely to be of value in the management of the patient.

## Concluding remarks

Due to its low volatility, mustard is persistent in the environment. It persists for shorter periods of time in a hot climate, but reaches higher vapor concentrations more rapidly. In temperate areas mustard may persist for more than 1 week, but in desert conditions, persistence is reduced to about 1 day. Mustard will bind to vegetation for days to weeks (USACHPPM, 2001b). Detection tubes can be used to monitor airborne levels of mustard gas (IARC, 1975).

The potential for secondary contamination is high. Rescue personnel must wear protective clothing, eye protection and a respirator (HSDB, 2005). Mustard gas penetrates wood, leather, rubber and paints. Medical personnel treating mustard-exposed patients have developed toxicity.

## LEWISITE

### Background

Lewisite ( $C_2H_2AsCl_3$ ) is a substituted arsine. Lewisite was first synthesized in 1918 by a research team headed by U.S. Army Captain W.L. Lewis. It is an oily vesicant (blister-causing) liquid with potential terrorist use. Lewisite smells like geraniums. Pure Lewisite is colorless, but impurities and age cause the color to darken (amber to black or violet to brown, to olive-green) (HSDB, 2005). Lewisite remains a liquid at low temperatures and is persistent in colder climates. It hydrolyzes rapidly, making it difficult to maintain a biologically active concentration on a humid day (Sidell *et al.*, 1997; AAR, 2000; Lewis, 2000; HSDB, 2005). The synthesis of Lewisite involves adding arsenic trichloride to acetylene, and using aluminum chloride as a catalyst. This results in a mixture of about 20% Lewisite, other arsine compounds and an explosive component. Lewisite can be dispersed in air as a very fine droplet spray over a large distance (Grant and Schuman, 1993; Lewis, 2000).

### Pharmacokinetics/toxicokinetics

Lewisite can cause systemic signs when ingested, inhaled or when absorbed dermally or ocularly (Sidell *et al.*, 1997; HSDB, 2005). Inhalation of vapor causes

immediate pain and if high enough concentrations are inhaled, death can be seen within 10 minutes (DeRosa *et al.*, 2002). Dermal absorption occurs within 3 to 5 minutes, especially following liquid exposures (Sidell *et al.*, 1997). The volume of distribution of arsenic after Lewisite administration is several liters/kilogram, indicating extensive tissue distribution (HSDB, 2005). A distribution study using rabbits revealed that the liver, lungs and kidneys had the highest concentration of arsenic after Lewisite administration (greater than seven times blood concentration). Arsenic can cross the placenta and is passed into the milk, and nursing animals may be at risk (Barlow and Sullivan, 1982).

Animal studies showed that excretion of Lewisite oxidation products into the bile caused focal necrosis of the liver and necrosis of biliary vessel mucosa with peribiliary hemorrhages (Munro *et al.*, 1999). The same study in rabbits found that arsenic was eliminated with a half-life in blood of 55 to 75 hours (HSDB, 2005). The excretion of oxidized Lewisite products into the bile by the liver may result in injury to the intestinal mucosa (Munro *et al.*, 1999).

## Mechanism of action

Besides being a vesicant, Lewisite is an arsenical compound which causes systemic effects. Lewisite directly effects enzyme systems. The exact mechanism of action is unknown, but it inhibits a variety of enzymes (pyruvic oxidase, alcohol dehydrogenase, succinic oxidase, hexokinase and succinic dehydrogenase) (DeRosa *et al.*, 2002). Lewisite binds with thiol groups on these enzymes, resulting in decreased ATP production. Ocular injuries following Lewisite exposure are due in part to the liberation of hydrochloric acid. Deep penetration of Lewisite into the cornea and aqueous humor causes rapid necrosis (Goldfrank *et al.*, 1998).

Lewisite causes increased capillary permeability. Systemic absorption and increased permeability can cause a significant loss of blood plasma volume and is called "Lewisite shock" since it is similar to that of shock observed in severe burns. The leakage of fluid into the extravascular space results in hypotension (Sidell *et al.*, 1997). The exact mechanism of increased capillary permeability is not known. Theories include a capillary dilating material released from skin or tissue, or alternatively, enhanced permeability from an interference with the metabolism of capillary endothelial cells (Goldman and Dacre, 1989). Lung capillaries appear to be the most affected due to absorption via the respiratory tract and first pass through the lungs following dermal exposure. Pulmonary edema or acute respiratory distress syndrome can develop (Sidell *et al.*, 1997).

RTECS (2006), Sidell *et al.* (1997) and DeRosa *et al.* (2002).

## Toxicity

Due to its method of dispersal (bursting charge of explosive), the main routes of absorption are dermal and respiratory. Lewisite first acts as a vesicant, then as a pulmonary irritant and finally as a systemic poison. Lewisite is similar to mustard gas in that it damages the skin, eyes and airways; however, it differs in that its clinical effects appear within seconds of exposure and it is about 10 times more volatile than mustard gas (Budavari, 2000). Exposure to Lewisite is very painful, in contrast to mustard. See Table 8.3 for LD<sub>50s</sub> of various species by different routes of exposure.

Dermal contact results in immediate pain. Both vapor and liquid Lewisite can penetrate skin. Reddening of the skin becomes evident within 15 to 30 minutes after exposure (EPA, 1985a; Sidell *et al.*, 1997; Pohanish, 2002). Evidence of tissue destruction (grayish epithelium) will be present within minutes of skin contact (Goldman and Dacre, 1989; Sidell *et al.*, 1997). Severe blisters develop within 12 hours after exposure. The blisters may rupture, usually about 48 hours after occurrence, with copious amounts of fluid seeping from the site. With dermal exposure, as little as 0.5 mL may cause severe systemic effects, and 2 mL may be lethal. Severe edema can be seen due to the Lewisite's increased capillary permeability. Dermal burns are generally deeper than those with mustard gas. Healing occurs much faster than with sulfur mustard-induced lesions and is generally complete within 4 weeks.

Ocular contact causes immediate pain, lacrimation and blepharospasm. Permanent blindness may occur if eye exposure occurs for more than one minute without rapid decontamination (EPA, 1985a; Pohanish 2002). A small droplet (1 µl) can cause perforation and loss of vision (Sidell *et al.*, 1997).

Inhalation of the Lewisite vapor may result in irritation to nasal passages, profuse nasal discharge and violent sneezing (HSDB, 2005). Inhalation of 6 ppm can be lethal (USACHPPM, 2001c). Following inhalation of vapor, coughing and hemoptysis commonly occurs (Sidell *et al.*, 1997; HSDB, 2005). Lesions following Lewisite inhalation are similar to the lesions produced by mustard gas exposures. Dogs that inhaled lethal doses died of necrotizing pseudomembranous

laryngotracheobronchitis (Goldman and Dacre, 1989). A thick membrane was noted in the nostrils, larynx and trachea with purulent bronchitis. Edema, hemorrhage and emphysema were seen in the lungs (Goldman and Dacre, 1989). Death can occur within 10 minutes with high concentrations (EPA, 1985a).

Unlike arsenic or mustard gas, Lewisite does NOT cause damage to the bone marrow or immunosuppression (Sidell *et al.*, 1997). Even though Lewisite is a substituted arsine, it also does not appear to directly cause hemolysis of the red blood cells (HSDB, 2005). Hypovolemia, secondary to fluid loss, can be severe enough to cause renal dysfunction. Arrhythmias may occur as a result of hypovolemia rather than a direct toxic effect of Lewisite on the myocardium. Lewisite was fetotoxic to rats and rabbits, but not teratogenic (Goldman and Dacre, 1989; RTECS, 2006). It is a suspected carcinogen due to its arsenic content. Lewisite blood levels are not clinically useful, but an arsenic blood level below 7 µg/100 ml is considered normal.

## Treatment

Move animals to fresh air and monitor for coughing and respiratory distress. Monitor blood gases and SpO<sub>2</sub> in patients with significant exposures. If coughing or difficulty breathing develops, administer oxygen and assist ventilation as needed. Bronchospasm should be treated with inhaled beta agonists and possibly corticosteroids. Monitor electrolytes and PCV as animals can become hemoconcentrated. Crystalloids should be given with caution not to overhydrate the patient (Goldfrank *et al.*, 1998). Consider urinary alkalinization and maintain good urine output. Monitor for liver and kidney failure and secondary infection.

Emesis is not recommended due to the irritant and vesicant nature of Lewisite. Dilute oral ingestions with milk or water. Activated charcoal is of unknown benefit in Lewisite ingestion and as severe irritation or vesication (blistering) of the esophagus or gastrointestinal tract is likely to occur it is not recommended. Endoscopy may be used to determine the extent of injury. Perforation and stricture formation may occur after ingestion.

Flush eyes with copious amounts of tepid water for at least 15 minutes. A 5% BAL (dimercaprol, British Anti-Lewisite) compounded ophthalmic ointment applied within 2 minutes may prevent a significant reaction. Treatment at 30 minutes will lessen the ocular reaction but does not prevent permanent damage (Goldfrank *et al.*, 1998).

Animals should be rinsed with copious amounts of water. A 5% solution of sodium hypochlorite (diluted liquid household bleach) should be used as soon as possible on contaminated skin. Topical application of a 5%

BAL ointment within 15 minutes of an exposure has been reported to be effective in diminishing the blistering effects of Lewisite (Smith, 1999). Wash BAL ointment off after 5 minutes. The ointment may cause stinging, itching or urticaria. Burns should be managed as discussed previously under mustard gas. Pain control is very important.

Chelation is indicated if there is coughing, dyspnea, pulmonary edema or skin burns larger than palm size (Goldfrank *et al.*, 1998). BAL is an effective arsenic chelator, but requires painful deep intramuscular injections and has numerous side effects (hypertension, tachycardia, vomiting, lacrimation, sweating). BAL will increase the clearance rate of arsenic, but it is contraindicated in animals with liver damage. 2,3-Dimercaptosuccinic acid (DMSA, Succimer<sup>®</sup>) appears to be a very effective arsenic chelator in animals (Graziano *et al.*, 1978). DMSA is an oral agent and is relatively non-toxic. It may be used following BAL. 2,3-Dimercapto-1-propanesulfonic acid (DMPS) is related to DMSA and is used for heavy metal poisoning, especially in Europe. It has been effective in protecting rabbits from the lethal effects of Lewisite (Aposhian *et al.*, 1982).

Urine arsenic levels may be tested using several methods. Urinary arsenic levels of <100 µg are considered normal (Proctor and Hughes, 2004). Concentrations between 0.7 and 1.0 mg/L indicate a potentially harmful exposure.

## Concluding remarks

Lewisite can remain in the environment for about 1 day. It reacts with water to yield a solid arsenoxide that also has vesicant properties. When in contact with strong alkalis, Lewisite is decomposed to less harmful substances. The potential for secondary contamination is high and material spilled on clothing may be transferred to rescuers or medical personnel. Lewisite is considered a terrorist threat as it is easy to produce and has a quick onset of signs. Carcasses should be buried deeply (away from water supplies), rendered or incinerated to insure safety of the food supply.

## PHOSGENE OXIME

### Background

Phosgene oxime (Agent CX, "Nettle Rush," CHCl<sub>2</sub>NO) is a halogenated oxime used as a blistering agent in chemical warfare. Other halogenated oximes include diiodoformoxime, dibromoformoxime and monochloroformoxime, but phosgene oxime is the most irritant of the group

and the only one considered a terrorist warfare threat. Phosgene oxime can be found as a liquid or as a colorless, low-melting point crystalline solid, readily soluble in water. The solid form can produce enough vapor to cause symptoms. Phosgene oxime has an unpleasant, peppery and irritating odor. Phosgene oxime is not a true vesicant as it does not cause skin blisters but it does have a rapid dermal corrosive effect. It can be dispersed as a liquid or vapor causing almost immediate tissue damage upon contact.

### Pharmacokinetics/toxicokinetics

Absorption in both dermal and inhalational exposures is complete and rapid (within seconds) (Sidell *et al.*, 1997). Dermal lesions form within seconds. Phosgene will dissolve in sweat and move to other nonexposed areas of the body as it is soluble in water (DeRosa *et al.*, 2002). Pulmonary edema can be evident on thoracic radiographs within 2 hours of high-dose exposure, 4 to 6 hours of moderate exposure and approximately 8 to 24 hours after low-dose exposure (Sidell *et al.*, 1997).

### Mechanism of action

The exact mechanism action is unknown, but it has been proposed that phosgene oxime reacts with SH and NH<sub>2</sub> groups (U.S. Army, 1996; Sidell *et al.*, 1997). Phosgene oxime exerts its greatest effects in the first capillary bed it encounters.

### Toxicity

Both liquid and vaporous phosgene oxime cause intense, immediate pain and local tissue destruction on contact with skin, eyes and mucous membranes (Sidell *et al.*, 1997). Damage to the eyes, skin and airways is similar to that caused by mustard gas. Following dermal contact with either the liquid or vapor, grayish tissue damage may be seen within several minutes. The damaged areas are erythematous and extremely painful. Within one hour, the area becomes edematous. Browning of the skin and blistering occurs the next day. In about 3 weeks, desquamation, necrosis, crust formation and purulent exudate occur. Pain can last for several days. Skin irritation begins at 0.2 mg/min/m<sup>3</sup> (12 seconds) for humans and is intolerable 3 mg/min/m<sup>3</sup> (1 minute) (USACHPPM, 2001d).

Phosgene oxime is very irritating to the eyes. Very low concentrations can cause lacrimation, inflammation and temporary blindness, and high concentrations can cause

permanent corneal lesions and blindness (U.S. Army, 1996; Sidell *et al.*, 1997; USACHPPM, 2001d). Inhalation or oral absorption may cause respiratory tract irritation, dyspnea and pulmonary edema. The non-cardiogenic pulmonary edema may occur after a several hour delay. Death is due to respiratory arrest.

### Treatment

There is no antidote for phosgene oxime exposure. Move animals into fresh air. Emesis is not recommended after oral ingestion because of the irritant and corrosive effects of phosgene oxime. Immediately dilute oral ingestions with milk or water. Activated charcoal is also not recommended after ingestion, since the primary toxicity is expected to be a local corrosive injury rather than systemic effects from absorption. Charcoal may also obscure endoscopy findings and induce emesis.

Flush eyes with tepid water until pH returns to neutrality and remains so for 30 minutes after irrigation is discontinued (Brodovsky *et al.*, 2000). Decontamination after ocular exposure is critical since phosgene oxime is absorbed within seconds. Corneal ulcers should be treated with mydriatic cycloplegics to prevent synechiae development (Grant and Schuman, 1993; Brodovsky *et al.*, 2000). For more severe corneal lesions, topical steroids, citrate, ascorbate and tetracycline or doxycycline may be used to aid in re-epithelialization.

The skin should be flushed with large volumes of water and mild soap. As phosgene oxime reacts so quickly with tissue, decontamination is not expected to be entirely effective after pain has been produced. Chloramine and phenol towelettes are ineffective for dermal decontamination. Isotonic sodium bicarbonate or 0.5% hypochlorite may remove phosgene oxime that has not yet reacted with tissue. Ulcerated skin lesions should be treated just like a thermal burn. Topical silver sulfadiazine is recommended (Roberts, 1988). Healing of dermal lesions can take from 1 month to over a year (U.S. Army, 1996; Sidell *et al.*, 1997). Both sheep and horses should receive tetanus prophylaxis. Other species should be vaccinated at the veterinarian's discretion. Large amounts of opioid analgesics may be needed to help control pain.

Monitor arterial blood gases, pulse oximetry and thoracic radiographs in patients following significant exposures. Non-cardiogenic pulmonary edema may take 12–24 hours to develop. If dyspnea develops, administer 100% humidified oxygen, perform endotracheal intubation and provide assisted ventilation as required. Beta adrenergic agonists may help if bronchospasm develops. Administer IV fluids but ensure that the animal does not become overhydrated (Hoffman, 2002).

## Concluding remarks

Phosgene oxime is considered nonpersistent in the environment. It hydrolyzes rapidly in aqueous alkaline solutions. The potential for secondary contamination is high. Veterinary personnel should wear aprons, rubber gloves and masks when treating decontaminated patients to avoid self-contamination. Phosgene oxime is of interest to terrorists as it penetrates garments and rubber much more quickly than other chemical warfare agents. Phosgene oxime can also be mixed with other chemical warfare agents (e.g., VX). The phosgene oxime will cause skin damage which will increase the dermal absorption of the second agent.

## CYANIDE AND HYDROGEN CYANIDE

### Background

Cyanogen and cyanogen halides (cyanogen bromide, cyanogen chloride, cyanogen iodide) have been used historically as military chemical warfare agents (Barr, 1985; ACGIH, 2005). Today cyanide is most likely to be used for a terrorist weapon in the form of hydrogen cyanide or cyanogen chloride.

Hydrogen cyanide (Agent AC, HCN, prussic acid) is a colorless gas with a faint bitter almond-like odor (ACGIH, 2005). Hydrocyanic acid is the liquefied form of hydrogen cyanide (Lewis, 1997). Cyanogen chloride (Agent CK, ClCN) is either a colorless irritant gas or liquid with a pungent odor. It was developed to be slightly heavier than air and to have greater environmental persistence. It can release hydrogen chloride and hydrogen cyanide when it contacts water, acids or by thermal decomposition. The water soluble salt forms (calcium cyanide, sodium cyanide and potassium cyanide) will form HCN gas when mixed with a strong acid.

Animals with cyanide poisoning may have an odor of bitter almonds in their gastric or ruminal contents or expired breath. The ability to smell the bitter almond-like odor of cyanide is genetically determined, and 20 to 60% of the population cannot detect its presence (Hall and Rumack, 1986). Cyanide and related compounds are classified as blood agents.

### Pharmacokinetics/toxicokinetics

Cyanide and hydrogen cyanide can be absorbed by inhalation, ingestion, ocularly and through intact skin (Ballantyne, 1983; Hall and Rumack, 1986). Cyanide rapidly diffuses into tissues and irreversibly binds to its target sites. Dermal absorption of significant amounts of

hydrogen cyanide gas has not been reported. There have been no reports of systemic poisoning in humans ocularly exposed to cyanide; however, rabbits have died following ocular exposure to NaCN, KCN and HCN.

Cyanide is distributed to all organs and tissues. The concentration of cyanide in red cells is greater than that in plasma by a factor of 2 or 3 (HSDB, 2005). Cyanide accumulates in neural tissue. It preferentially accumulates in the hypothalamus, with levels about 40% higher compared to the hippocampus, cerebellum and cortex (Borowitz *et al.*, 1994). In acute cyanide intoxication, there are no specific pathologic changes.

Cyanide is metabolized by rhodanase in the liver to thiocyanate (Hall and Rumack, 1986). This reaction complexes cyanide with endogenous sulfur or sulfur supplied from the sodium thiosulfate antidote. Once thiocyanate is formed it is excreted mainly in the urine. Half-life for the metabolism of cyanide to thiocyanate is 20 minutes to 1 hour (Feldstein and Klendshoj, 1954). In animals, the dose of cyanide that produces signs is very close to the lethal dose and death can occur within seconds to minutes.

### Mechanism of action

Cyanide causes its toxicity by forming a stable complex with ferric iron ( $\text{Fe}^{3+}$ ) in cytochrome oxidase enzymes. Since oxygen is unable to re-oxidize the reduced cytochrome a3, this inhibits cellular respiration, oxygen utilization and ATP production, resulting in deprivation of oxygen to the body at the cellular level (Way *et al.*, 1988). In the brain cyanide decreases oxidative metabolism, increases glycolysis and inhibits brain glutamic acid decarboxylase, thereby decreasing GABA (Bingham *et al.*, 2001). The corpus callosum, hippocampus, corpora striata and substantia nigra are commonly damaged in cyanide poisoning (Grandas *et al.*, 1989).

Early in cyanide toxicosis, CNS, respiratory and myocardial depression also contribute to decreased oxygenation of the blood and decreased cardiac output (Hall and Rumack, 1986). There is also evidence of lipid peroxidation by measurement of elevated levels of conjugated dienes in mouse brain and kidneys at 15 and 30 minutes after cyanide exposure (Ardelt *et al.*, 1994). Cyanide salts are irritating upon ingestion and can cause corrosion of the oral, esophageal or gastric mucosa (HSDB, 2005).

### Toxicity

Signs following acute cyanide exposure include syncope, or CNS stimulation, dizziness, dyspnea, seizures, paralysis, apnea and coma (Vogel *et al.*, 1981; Hall and Rumack, 1986). Tachypnea and hyperpnea are followed rapidly by

ACGIH (2005), Bingham *et al.* (2001), Budavari (2000), HSDB (2005), ITI (1995), Lewis (2000), OHM/TADS (2005) and RTECS (2006).

respiratory depression. Signs of severe hypoxia without cyanosis can suggest the diagnosis. Signs in birds are similar to those in mammals. Chickens will pant, have rapid eye blinking, excess salivation and lethargy (Wiemeyer *et al.*, 1986). Mydriasis is common in severe poisonings and blindness may occur from cyanide-induced damage to optic nerves and retina (Grant and Schuman, 1993; Vogel *et al.*, 1981). Nausea, vomiting and abdominal pain may occur, especially after ingestion of cyanide salts (Vogel *et al.*, 1981; Hall and Rumack, 1986; Singh *et al.*, 1989). Metabolic acidosis and lactic acidosis are frequent metabolic derangements. Blood gases show a decreased arterial-venous oxygen saturation difference due to the cellular inability to extract oxygen (Paulet, 1955; Graham *et al.*, 1977).

The blood, both arterial and venous, becomes cherry red from accumulated oxyhemoglobin (Lewis, 2000; Bingham *et al.*, 2001). The skin may also be a bright pink color from the high concentration of oxyhemoglobin in the venous return (HSDB, 2005). On fundoscopic exam, retinal arteries and veins will appear equally red. A reduced arterio-central venous measured oxygen saturation difference may be seen due to the same cellular inability to extract oxygen. This arterialization of venous blood gases occurs early in the process of cyanide poisoning. Tachycardia and hypertension may be seen in the initial phases of cyanide poisoning followed by bradycardia and hypotension in the late phases. Cyanide exposure can produce death within minutes. See Table 8.4 for LD<sub>50</sub>s of HCN by various routes.

Cyanide can be measured in blood. No symptoms are expected at concentrations less than 0.2mg/L, tachycardia can be seen at 0.5–1.0mg/L, obtundation at 1.0–2.5mg/L, coma and respiratory depression at levels greater than 2.5mg/L and death with blood levels greater than 3mg/L (Graham *et al.*, 1977). No adverse reproductive studies were found for cyanide or hydrogen cyanide, but in laboratory animals, cyanide compounds did cause resorptions, malformations and teratogenic effects in offspring (Willhite, 1983).

## Treatment

Move animals to fresh air. Emesis is not recommended due to the rapid progression of the clinical signs and

potential for seizures, coma or apnea. Activated charcoal may be beneficial if administered immediately after ingestion as the absorption of cyanide is rapid. Flush eyes for at least 15 to 20 minutes with tepid water. Wash all contaminated animals thoroughly with soap and water.

Monitor arterial blood gases and serum electrolytes. Administer 100% humidified oxygen with assisted ventilation if needed to maintain an elevated pO<sub>2</sub>. Hyperbaric oxygen therapy is approved for cyanide poisoning by the Undersea Medical Society (Myers and Schnitzer, 1984). It has been suggested to improve clinical outcome, but experimental animal studies have been questionable (Way *et al.*, 1972). For severe acidosis (pH < 7.1) administer sodium bicarbonate, but acidosis may be difficult to correct prior to administration of antidotes in cyanide toxicosis (Hall and Rumack, 1986). Control seizures with benzodiazepines or barbiturates.

Cyanide toxicosis usually occurs and progresses so rapidly that treatment is rarely administered soon enough to be effective. Antidotal agents should be used if the animal is in respiratory distress or a coma. There are several different antidotal agents that can be used. Hydroxocobalamin, a vitamin B<sub>12</sub> precursor, is a cobalt containing chelator. Hydroxocobalamin reverses cyanide toxicosis by combining with cyanide to form cyanocobalamin (vitamin B<sub>12</sub>) (Hall and Rumack, 1987). It has been shown to be effective in treating cyanide-poisoned laboratory animals and has the advantage of producing neither methemoglobinemia nor hypotension, as sodium nitrite does.

Another choice for treatment of cyanide poisoning utilizes several steps. Sodium nitrite is given IV over 15–20 minutes, as soon as vascular access is established. Quick administration can cause hypotension. Sodium nitrite reacts with hemoglobin in the red blood cells forming methemoglobin. The methemoglobin will combine with free cyanide to form cyanomethemoglobin. If possible, monitor methemoglobin levels during nitrite administration. The goal is to maintain methemoglobin levels below 30% (Hall and Rumack, 1986). Follow sodium nitrite with IV administration of sodium thiosulfate. Sodium thiosulfate supplies sulfur for the rhodanase reaction. Thiocyanate is formed and excreted in the urine. Oxygen, combined with traditional nitrite/thiosulfate therapy, provides better results than thiosulfate alone (Way *et al.*, 1972). It is believed that oxygen may reverse the cyanide-cytochrome oxidase complex and aid in the conversion to thiocyanate following thiosulfate administration.

Dicobalt-EDTA (Kelocyanor®) is also highly effective in chelating cyanide. It is used clinically in Europe, Israel and Australia, but it is not available in the United States (Hillman *et al.*, 1974). Another methemoglobin-inducing agent used in some European countries is 4-dimethylaminophenol hydrochloride (4-DMAP). It has a more

rapid onset of methemoglobin production than sodium nitrite. Methemoglobin peaks at 5 minutes after 4-DMAP versus 30 minutes after sodium nitrite. 4-DMAP is coadministered with thiosulfate. Excessive methemoglobin production can be a major complication and hemolysis may occur with therapeutic doses (van Dijk *et al.*, 1986).

Animal studies to identify alternate cyanide antidotes have tested stroma-free methemoglobin solutions, alpha-ketoglutaric acid, chlorpromazine, hydroxylamine, phenoxybenzamine, centrophenoxine, naloxone hydrochloride, etomidate, para-aminopropiophenone and calcium-ion channel blockers (Ashton *et al.*, 1980; Amery *et al.*, 1981; Dubinsky *et al.*, 1984; Leung *et al.*, 1984; Ten Eyck *et al.*, 1985; Johnson *et al.*, 1986; Bright and Marrs, 1987; Yamamoto, 1990; Budavari, 2000). These antidotes have shown some promise in the laboratory setting, but have not been tried during actual poisoning situations.

Blood cyanide levels can be useful in confirming the diagnosis. However, unless the results are available within a reasonable time, it is not clinically useful. Cyanide can be measured by several methods but most take several hours to complete. Biological specimens can be tested using spectroscopy, gas chromatography, gas-liquid chromatography, paper chromatography, ion-specific electrode, fluorimetric, microdistillation and paper strip (Groff *et al.*, 1985; Fligner *et al.*, 1992; HSDB, 2005). Cyanide and thiocyanate levels can be measured in timed urine collections to provide information on cyanide clearance, but it is rarely done clinically. Handling of samples is very important due to the volatile nature of HCN. The loss of cyanide from specimens can be minimized by rapid analysis after death, collection of blood from a closed source, storage in a fluoride-oxalate tube with minimal dead space and frozen at minus 20°C (Bright *et al.*, 1990).

## Concluding remarks

Because HCN is lighter than air, it has a long half-life in air. However, HCN rapidly disperses and is diluted to non-toxic concentrations. Cyanide does not concentrate in soil or plant material, but can mix with water. Water converts HCN gas to HCN liquid. Treat contaminated water with ozone, hydrogen peroxide or calcium or sodium hypochlorite bleach. The potential for secondary contamination of rescue personnel is high. Boots, gloves, goggles, full protective clothing and a self-contained positive pressure breathing apparatus are needed (AAR, 2000).

As a chemical warfare agent, cyanide is not easy to disseminate; however, it is widely available which increases the chances of its use in terrorist activities (Burklow *et al.*, 2003). Cyanide works much better as a terrorist weapon in an enclosed space.

## MILITARY NERVE AGENTS

### Background

Military nerve agents are probably the most poisonous of the known chemical warfare agents and are sufficiently toxic that even a brief exposure may be fatal. They were originally synthesized by the Germans during WWII in search of alternatives to the embargoes against insecticidal nicotine. Military nerve agents are rapidly acting, anticholinesterase organophosphate (OP) compounds, and are more potent than organophosphate insecticides. Military nerve agents contain a C-P bond that is unique and very resistant to hydrolysis, except in highly alkaline solutions. At ambient temperatures, nerve agents are viscous liquids, not gases.

Military nerve agents are generally divided into "G" agents and "V" agents. The "G" agents (tabun, sarin, soman) were developed during WWII and are called "G" agents because they were first synthesized in Germany. The "G" agents are very volatile and present a vapor hazard. The vapors are more dense than air, thus they stay close to the ground (Garigan, 1996). Tabun (Agent GA,  $C_5H_{11}N_2O_2P$ ) was the first of the "G" agents to be synthesized in 1936, followed by sarin (GB,  $C_4H_{10}FO_2P$ ) in 1938 and soman (GD,  $C_7H_{16}FO_2P$ ) in 1944 (Sidell *et al.*, 1997).

Tabun is the easiest of the "G" agents to manufacture. It is a fruity-smelling (like bitter almonds) combustible colorless to brownish liquid. Contact with bleaching powder generates cyanogen chloride (EPA, 1985c). It may also undergo hydrolysis in the presence of acids or water, releasing hydrogen cyanide (Munro *et al.*, 1999; Budavari, 2000; HSDB, 2005). Sarin is a colorless liquid with almost no odor in its pure state (Budavari, 2000). Soman is a colorless liquid with a fruity or camphor odor. Soman can release hydrogen fluoride when in contact with acids.

The "V" agents ("V" for venomous) were developed in 1954 in the United Kingdom and are more stable than the "G" agents (Sidell *et al.*, 1997). "V" agents, such as VX, contain a sulfur group and are alkylphosphonothiolates; they are more toxic and persistent on surfaces than G-series agents. VX ( $C_{11}H_{26}NO_2PS$ ) is a nonvolatile, amber colored, odorless liquid.

### Pharmacokinetics/Toxicokinetics

Nerve agents can be absorbed following ocular exposure, oral ingestion, inhalation and dermal contact (HSDB, 2005; RTECS, 2006). These nerve agents are absorbed without producing any irritation or other sensation on the part of the exposed person or animal. Inhalation of military nerve agents will have initial effects on the airways within seconds. Inhalation of a large amount of the vapor will result in sudden loss of

consciousness, apnea, flaccid paralysis and seizures within seconds to 2–3 minutes (Sidell *et al.*, 1997). Peak effects are seen within 20–30 minutes and death is usually due to respiratory failure (Berkenstadt *et al.*, 1991). Dermal exposures to nerve agents have a slower onset of action. Exposure to a large drop or more will result in clinical effects within 30 minutes but with small drops a delay of up to 18 hours can be seen. With ingestion, initial symptoms begin in 20 to 30 minutes and are usually gastrointestinal. There is no taste to solutions containing nerve gas agents (Grob, 1956).

Distribution in the body is slightly different for each of the nerve agents. Distribution of sarin is to the brain, liver, kidney and plasma of mice (Little *et al.*, 1986). Radiolabeled soman was evenly distributed throughout the mouse brain after IV administration, with higher levels in the hypothalamus (Wolthuis *et al.*, 1986). Tabun was also found in high concentrations in the hypothalamus after IV administration in mice (Hoskins *et al.*, 1986). An unusual feature of soman toxicity is its apparent storage in body “depots” and release over time. This results in eventual death in animals who survive the initial dose of soman (Wolthuis *et al.*, 1986).

The military nerve agents differ from other OPs in the rapidity of “aging” of the OP-enzyme complex. “Aging” is thought to be due to the loss of an alkyl group, whereby the inhibitor–enzyme complex becomes resistant to reactivation (Young *et al.*, 1999). The half-life ( $T_{1/2}$ ) of aging for soman is within minutes, for sarin is about 5 hours and for both tabun and VX is greater than 40 hours (Garigan, 1996).

The nerve agents are hydrolyzed by plasma and tissue enzymes to their corresponding phosphoric and phosphonic acids. Oxidative enzymes are also involved in metabolism (HSDB, 2005). Sarin is hydrolyzed in the body to isopropyl-methylphosphonic acid (IMPA). IMPA in mice studies was generally present at 20-fold higher concentrations than sarin in most tissues; exceeding sarin by four times in the brain (Little *et al.*, 1986). In mice studies, the majority of administered radioactive sarin was detoxified and excreted by the kidneys (Little *et al.*, 1986). Mouse studies reveal that approximately 50% of injected soman is converted to free pinacolyl-methylphosphonic acid within 1 minute, and the half-life of this metabolite is less than 1 hour (Reynolds *et al.*, 1985). Soman is mainly eliminated via enzymatic hydrolysis, in competition with binding to target acetylcholinesterase (HSDB, 2005).

## Mechanism of action

Organophosphates (OPs) competitively inhibit acetylcholinesterase (AChE) by binding irreversibly to its esteric site (phosphorylation). Inhibition of the AChE

enzyme results in accumulation of acetylcholine and excessive stimulation at muscarinic, nicotinic and CNS cholinergic sites. Increased acetylcholine at autonomic neuro-effector junctions results in increased smooth muscle contractions and secretions, but its effect at skeletal muscle junctions is initially stimulatory (fasciculations), followed by inhibitory (muscle weakness, paralysis). The effects on the sino-atrial node of the heart is inhibitory, causing bradycardia (Namba *et al.*, 1971). Acetylcholine accumulation in the CNS can cause ataxia, seizures and coma. These high levels of ACh induce massive neuronal deaths in various brain areas, particularly in limbic and cortical structures. Death from nerve agents is due to paralysis of the diaphragm, airway obstruction from increased tracheobronchial secretions and depression of the CNS respiratory center (Garigan, 1996).

VX is also thought to possibly react directly with receptors of other neurotransmitters, such as norepinephrine, dopamine and GABA. VX appears to have CNS effects that are unrelated to AChE activity and these agents may produce prolonged effects following convulsive doses (Young *et al.*, 1999).

## Toxicity

Symptoms of acute exposure to OPs may include muscarinic, nicotinic and CNS signs. The muscarinic effects include sweating, hypersalivation, bronchoconstriction and increased bronchial secretions, miosis, bradycardia, hypotension, vomiting and diarrhea, and urinary and fecal incontinence. The nicotinic effects include fasciculations, convulsions and weakness of muscles (including the diaphragm). The CNS effects of nerve agents include restlessness, anxiety, headaches, seizures and coma (Garigan, 1996). Effects after inhalation begin within seconds to minutes post exposure. Death can occur within minutes from inhibition of acetylcholinesterase function.

The “G” nerve gases do not readily penetrate intact skin, but toxicity significantly increases if the skin becomes permeable. Dermal toxicity of VX is high, even through intact skin as the liquid does not evaporate quickly (Berkenstadt *et al.*, 1991; Sidell *et al.*, 1997). With dermal exposures, a very small drop on the skin may cause sweating and fasciculations at the site, starting within 18 hours of exposure. A larger drop may cause loss of consciousness, seizures, apnea and flaccid paralysis, with effects beginning within 30 minutes (Sidell *et al.*, 1997). Liquid tabun in the eye can result in death nearly as quickly as an inhaled dose (EPA, 1985c).

On a per weight basis, toxicity in descending order is: VX > soman > sarin > tabun. As used, sarin is the most potent of the “G” nerve agents and VX is about three times more potent a respiratory agent than sarin. VX is

TABLE 8.5 LD<sub>50</sub> (mg/kg) for various nerve agents

RTECS (2006) and Sidell *et al.* (1997).

300 times more lethal than tabun on skin (Sidell *et al.*, 1997). See Table 8.5 for LD<sub>50</sub>s of the various nerve agents.

Plasma cholinesterase values usually recover in a few days or weeks, due to the irreversible nature of organophosphate inhibition. RBC AChE recovers more slowly (several days to 4 months) depending on the severity of the depression (Grob, 1956). Delayed neurotoxicity has not been reported in humans following nerve agent exposure. However, delayed peripheral neurotoxicity has been reported in animal studies. Soman, at a dose of 1.5mg/kg, produced severe delayed neuropathy in the atropinized hen assay (Willems *et al.*, 1984). No pre-natal mortality or fetal toxicity was noted in soman-poisoned rats or rabbits, even at doses producing significant maternal toxicity, but other nerve gases showed post-implantation mortality and fetotoxicity (HSDB, 2005; RTECS, 2006).

## Treatment

Remove animal from the toxic environment. Administer oxygen if needed. Intubation and ventilation may be necessary if signs progress. Flush eyes with copious amounts of tepid 0.9% saline or water for at least 15 minutes. Reactive skin decontamination lotion (RSDL) appears to be the best available dermal decontamination agent (Hanssen *et al.*, 2006). If RSDL is not accessible, wash all exposed animals three times with soap and water. The use of a dilute bleach solution (1:10 with water), ethanol or tincture of green soap may be more efficacious (Cancio, 1993).

Emesis is not recommended in oral ingestion due to the rapid development of signs. Activated charcoal might provide benefits even after a topical exposure. Control seizures with diazepam, methocarbamol or barbiturates as needed before proceeding with other treatments.

Atropine sulfate is a reversal agent. It is used for the treatment of muscarinic effects of nerve agent poisoning, but will not reverse nicotinic effects (muscular fasciculations and weakness). Atropine does not affect the

AChE–insecticide bond, but blocks the effects of accumulated acetylcholine at the synapse. Atropinization should be continued until the nerve agent is metabolized (Midtling *et al.*, 1985). Effects of overdosing with atropine include hyperthermia, tachycardia, inspiratory stridor, irritability and dilated and unresponsive pupils (Meerstadt, 1982).

Pralidoxime (2-PAM) can be used to treat the nicotinic signs. Pralidoxime is probably most effective when administered in the first 1 to 3 hours. Pralidoxime is not as effective in the treatment of soman poisoning, due to the quick “aging” (within minutes) of the compound (Sidell *et al.*, 1997). Since VX-inhibited cholinesterase ages slowly, administration of 2-PAM chloride is effective in reactivating the enzyme for up to 48 hours after exposure (Sidell and Groff, 1974).

In Belgium, Israel, the Netherlands, Scandinavia, Portugal and West Germany, obidoxime dichloride (Toxogonin, LUH6) is the favored oxime. It may be a less toxic and more efficacious alternative to pralidoxime in poisonings from organophosphates containing a dimethoxy or diethoxy moiety (De Kort *et al.*, 1988). HI-6 is an alternative oxime that has excellent acetylcholinesterase regenerating action with VX and very good action with sarin (GB). It has a good response to soman, but provides poor to no response following tabun exposures (Hoffman, 1999). HI-6 is given in conjunction with atropine and diazepam (Kusic *et al.*, 1991). Recent experimental evidence suggests that oximes of K series are very effective against OP nerve agents, although their potency in clinical trials has yet to be tested (Kuca *et al.*, 2009a, b).

With human exposures to nerve agents, autoinjectors (AtroPen<sup>®</sup>, Mark I<sup>®</sup>, Combopen MC<sup>®</sup>) are available for use. Most available autoinjectors combine atropine and pralidoxime. Autoinjectors are not used in veterinary medicine as they are not adaptable for different sized patients.

The “G” agents have been detected in urine and water using capillary gas chromatography (GC) and GC-MS (Okudera *et al.*, 1997; Kientz, 1998). Immunoassay has been used to detect VX in biological samples (Ci *et al.*, 1995). Nerve agent detection is not as clinically relevant as the measuring of acetylcholinesterase (AChE). AChE activity can be used as a diagnostic indicator or a screening test. The test can be run on plasma, serum or whole blood. AChE activity that is <70% of normal is generally associated with severe symptoms (Midtling *et al.*, 1985). Blood AChE does not always correlate well with clinical signs and poisoning has been diagnosed in patients with “normal” values.

## Concluding remarks

The “G” agents evaporate and disperse over several hours, they are nonpersistent in the environment (Garigan,

1996). In contrast, VX is an oily liquid that can remain in the environment for weeks or longer after being dispersed (Garigan, 1996; Sidell *et al.*, 1997; Munro *et al.*, 1999; Budavari, 2000). Environmental persistence is estimated to be 0.5–1 day for tabun, 1–2 days for soman, 5 days for sarin and several weeks for VX. Environmental cleanup of organophosphate spills depend on changing the pH to promote hydrolysis to inactive phosphate diester compounds (EPA, 1978). Contaminated soil can be treated with either alkaline substances (sodium carbonate, sodium bicarbonate, calcium hydroxide, calcium hydroxide and calcium carbonate) or chlorine-active compounds (sodium hypochlorite or calcium hypochlorite) (EPA, 1975).

Veterinarians and staff can be dermally exposed to contaminated animals. Rubber gowns, aprons and gloves along with respiratory protection must be worn. Once the animals are bathed, the risk of secondary contamination is low. Leather absorbs organophosphates and is extremely difficult to decontaminate. Leather collars, muzzles and other items should be incinerated.

The production of nerve agents is beyond the capabilities of most terrorist groups. Production requires a significant background in chemistry and outlay of capital. The production of sarin by the Aum Shinrikyo cult was estimated to take 1 year to make, involved 80 persons led by a PhD-level scientist and cost about \$30 million (Leitenberg, 1999).

# Regulatory considerations in veterinary toxicology

Lynn O. Post

**Disclaimer:** This chapter was written by Lynn O. Post in his private capacity. No official support or endorsement by the FDA is intended or should be inferred.

included in the list of references for the reader to consult more complete and/or updated information from Internet home pages of the respective federal agencies and other reliable organizations.

## INTRODUCTION

This chapter is organized into six sections: Section I: Food and Drug Administration and the Center for Veterinary Medicine; Section II: Environmental Protection Agency; Section III: U.S. Department of Agriculture; Section IV: Drug Enforcement Administration; Section V: Occupational Safety and Health Administration; and Section VI: Statutes, Regulations and Guidelines. Sections I through V describe the federal agencies that are important to animal health, including processes, organizational structure and mission, and selected programs. Testing methods and pharmacovigilance for the Center for Veterinary Medicine, the Environmental Protection Agency and the U.S. Department of Agriculture are described in Sections I through III. Pharmacovigilance is the emerging area of monitoring for unintended harmful effects of marketed animal health products.

This chapter is an overview of a complex and dynamic area that is under the constant influence of competing interests (consumer groups, industrial groups and professional organizations), new legislation and legal precedents, as well as a new generation of animal health products and issues. Appropriate Internet addresses are

## SECTION I. FOOD AND DRUG ADMINISTRATION AND THE CENTER FOR VETERINARY MEDICINE

### Creation and organization of the FDA and CVM

Animal drugs and medical devices are regulated by the Food and Drug Administration's (FDA) Center for Veterinary Medicine (CVM) under the Federal Food, Drug and Cosmetic Act (FFDCA). The FFDCA and FDA are widely recognized as the preeminent regulatory legislation and agency in the nation. The first Federal Food and Drug Act was passed in 1906. It prohibited interstate shipment of adulterated or misbranded food, drink and drugs, and was administered by the U.S. Department of Agriculture's (USDA) Bureau of Chemistry. In 1938 landmark broader legislation was passed requiring manufacturers to provide evidence of product safety before distributing new drugs. This legislation also provided authority to conduct manufacturing site inspections, establish tolerances for unavoidable contaminants and use court injunctions as enforcement tools. In 1940, FDA was transferred from USDA, ultimately becoming part

TABLE 9.1 Recent major animal health product-related amendments to the FFDCA

Amendment	Summary of changes
Generic Animal Drug and Patent Term Restoration Act (GADPTRA)	Enacted 1988.  Provides for approval of generic copies of animal drug products that have been previously approved and shown to be safe and effective. Provided for prescription status for animal drugs.
Animal Drug Use Clarification Act of 1994 (AMDUCA)	Allows veterinarians to prescribe extra-label uses of approved animal drugs and approved human drugs for animals under certain conditions. Allows FDA to restrict extra-label use in certain circumstances. Allows FDA to establish a safe level for a residue for such extra-label use by regulation or order and require the development of analytical methods for residue detection.
Animal Drug Availability Act of 1996 (ADAA)	Amended the definition of substantial evidence of effectiveness. Created a new category of drugs – “Veterinary Feed Directive Drugs.” Permitted a range of doses to appear on animal drug product labeling, rather than one optimum dose. Provided for Licensing of feed mills and eliminated the requirement for medicated feed applications.

of the Department of Health, Education and Welfare (DHEW), which became the Department of Health and Human Services (DHHS). During the early 1950s, a veterinary branch was established within the FDA's Bureau of Drugs. Subsequently, two major amendments to the FFDCA were passed. The Food Additive Amendments of 1958 expanded FDA's authority over animal food additives and drug residues in animal-derived foods. The Kefauver-Harris Drug Amendments of 1962 brought major changes to the FFDCA, requiring manufacturers to test new drugs for effectiveness before marketing them, and to report adverse drug events promptly to FDA. These requirements were also applied through a modified process to products already on the market. Recognizing the importance of animal health products the FDA established the Bureau of Veterinary Medicine (all Bureaus became Centers in 1984) in 1965. However, animal drugs were still regulated under three different sections of the FFDCA, either as new drugs, antibiotics or if labeled for food-animals, as food additives. Because this situation produced a regulatory scheme for animal drugs that was confusing and more complex than for human drugs, the Animal Drugs Amendments of 1968 were passed consolidating the various sections of the FFDCA that applied to animal drugs in one section (512) of the FFDCA. More complete discussions of the history of the FFDCA and CVM are available (Teske, 1995; FDA Center for Veterinary Medicine, 1999). More recent animal health product-related amendments to the FFDCA are given in Table 9.1 (FDA Center for Veterinary Medicine, 2000).

FDA is an agency within the DHHS. The senior official within FDA is the FDA Commissioner. The agency is organized by product responsibility into Centers: Center for Veterinary Medicine (CVM); Center for Drugs Evaluation and Research (CDER); Center for Biologics

Evaluation and Research (CBER); Center for Devices and Radiological Health (CDRH); and the Center for Food Safety and Nutrition (CFSAN). The FDA is also organized geographically into Regional Offices and component Districts where field staff are assigned.

### Approving and monitoring animal drugs

Under the FFDCA, the CVM is responsible for ensuring that animal drugs and medicated feeds are safe and effective for their intended uses and that food from treated animals is safe for human consumption. To accomplish its mission, the CVM is organized into pre-market review, post-market monitoring and research components. In addition, FDA field staff conduct inspections of FDA-regulated animal health industries and products. Prior to a product being marketed it must have an approved New Animal Drug Application (NADA). In order for an NADA to be approved there must be substantial evidence that the new animal drug is effective and safe for its intended uses under the conditions of use prescribed, recommended or suggested in the proposed labeling. In addition, methods, facilities and controls used for the manufacturing, processing and packaging of the drug must be shown to be adequate to preserve its identity, strength, quality and purity (Good Manufacturing Practices, 21 CFR 210 and 211). For food-animal products safety includes safety of drug residues in animal-derived food. Tolerances for residues of new animal drugs in food may be found in 21 CFR 556. Safety would also include an assessment of the effects of the proposed animal drug on the environment and on human health. Following approval, products are monitored to ensure safety and effectiveness and maintained under actual conditions of use.

## Testing methods for animal drugs

FDA has developed extensive detailed guidelines for the conduct of studies required to obtain approval to market products. This section provides a brief description of the animal safety and efficacy studies and human safety studies that may be performed. They are provided to familiarize the student with the general scope of information required for product approval, not to provide guidance in designing studies for product approval. The specific pertinent agency guideline should be consulted prior to designing a study protocol.

### **CVM target animal safety and product efficacy testing requirements**

#### *Introduction*

A veterinary drug sponsor must show that a drug is safe to use as described in the proposed labeling (21 CFR 514.1(b)(1) and 512(d) of the FFDCA; [FDA Center for Veterinary Medicine, 1989](#)). The information needed to determine a products' safety in the target species depends on several factors: proposed use, type of product, chemistry, intended species, breed and class of animal (calves versus mature ruminants), claims and previous use history. Existing data collected from previous studies are used to develop and refine protocols for toxicity studies. While the CVM target animal safety guideline is intended to provide general directions for acquiring essential information, all the data requirements for a standard target animal safety study are not required for every product, and special circumstances may require the collection of additional data that is not specified for the standard study.

#### *Good laboratory practices and general study requirements*

Laboratory studies in animals are conducted according to Good Laboratory Practice (GLP) regulations (21 CFR Section 58). Target animal safety studies are also subject to GLP regulations. The GLP regulations ensure that methods and procedures for collecting, processing and reporting data are standardized and verified for the entire study. GLPs ensure an adequate level of accuracy and quality control. Many GLP requirements are inherent in any well-designed scientific study. On the other hand, adherence to GLP standards does not guarantee the scientific validity of the study.

Since animal husbandry requirements often differ for laboratory animals and domestic animals, domestic animals utilized in clinical studies are not maintained under GLP conditions. Appropriate diagnostic tests, vaccinations, prophylactic and therapeutic treatments are completed prior to the treatment phase of the study. During this initial phase a complete physical examination is performed and baseline data are collected by a

qualified person. The test product formulation must be identical to the proposed marketed product. The route of administration should be the same as the proposed labeling; however, the toxicity or nature of the product may require a different formulation. For example, due to feed refusal, a drench of a product may be required instead of delivery of the drug through a medicated feed.

Data are collected at predetermined intervals during the trial. Clinical observations are recorded at specified intervals, usually twice a day, 7 days a week during the entire study or modified according to the study protocol. During the study appropriate clinical pathology procedures are conducted in all test groups, usually only half of the animals selected at random from each group at predetermined intervals. Histopathologic examinations may be required from all or a portion of the animals. Tissues from the highest treatment and control groups must be examined. If microscopic lesions are observed, corresponding tissues from the next lower treatment group are examined until a no observable effect level (NOEL) is established.

#### *Drug tolerance test*

Under controlled conditions, the target animal response to a toxic dose is characterized by clinical signs. Clinical signs include changes in behavior and appearance and gross lesions in animals that die during the study. Clinical pathology and histology data reveal physiological functions that are most readily affected by the drug. The duration of the toxicity studies may range from acute to chronic.

Target animal safety studies require systemic testing for new products or new chemical entities and additional animal species. They are not required for drugs administered locally, such as otic, ophthalmic, intramammary and intra-articular preparations. This does not apply to generalized dermal or topical drugs that may act systemically. The market formulation of a drug must be administered according to the proposed conditions of use. If volume or palatability becomes a limiting factor for administration, gavage, intravenous, multiple sites or incremental doses may be used. A vehicle control group must be included in the experimental design.

Usually, up to ten times (10×) the maximum proposed clinical dose is administered. The toxic dose (10×) may be reduced or increased in order to manifest toxic signs without causing death. The main purpose of the tolerance test is to characterize toxic signs which can be used to develop toxicity study protocols at lower doses (1×, 3× and 5×). The toxicity studies are used to design the clinical efficacy study protocol.

#### *Toxicity study*

The objectives of toxicity studies in target animal species are: (1) to demonstrate safety of the drug product under

condition of use, (2) to demonstrate signs and effects associated with toxicity and (3) to demonstrate a margin of safety at 5× or below ([FDA Center for Veterinary Medicine, 1989](#)). If the drug has a narrow margin of safety with an intended use in debilitated animals, safety studies in diseased animals may be necessary. This may require more animals per treatment group because of greater variability. Special studies may be requested by FDA, such as lameness, reproductive, dermal irritation, specific routes of administration, tissue disposition and combination drugs.

### ***FDA-required toxicological testing in food-producing animals***

#### *General considerations*

Studies must be conducted according to GLPs. For compounds used in food-producing animals, FDA is concerned with intermittent and chronic exposure of people to relatively low concentrations of residues. FDA tailors the type of toxicological testing needed to show safety for a specific compound. Factors, which are considered include the proposed use, the potential human exposure of the parent compound and/or its residues, as deduced by structure–activity relationships. Some compounds need only a minimum of testing; others may need very extensive studies in a number of diverse biological systems.

The purpose of the toxicology studies is to define the biological effect(s) of the sponsored compound and its quantitative limits. FDA generally asks that the sponsor (owner of the NADA), at a minimum, determines a dose of the compound that produces an adverse biological effect in test animals and a dose that does not produce any significant toxicological or pharmacological effect (NOEL). The spacing of the doses should provide an assessment of the dose–response relationship ([FDA Center for Veterinary Medicine, 2005](#)).

#### *Testing requirements*

FDA recommends the following studies as the minimum necessary for each sponsored compound:

- A battery of genetic toxicity tests.
- A 90-day feeding study in both a rodent species (usually the rat) and a non-rodent mammalian species (usually the dog).
- A two-generation reproduction study with a teratology component in rats. Two litters should be produced in each generation. If toxicity occurs at a lower dose, with a higher incidence, or with greater intensity in the second generation as compared to the first, then the study should include a third generation.

FDA may require the following additional studies, which should be conducted using an approved protocol:

- Chronic bioassays for oncogenicity in each of two rodent species when indicated by positive results in genetic toxicity tests.
- One-year feeding studies in a rodent species (usually the rat) and in a non-rodent species (usually the dog) are needed, when human residue exposure exceeds 25 µg/kg body weight/day. This daily intake is equivalent to 1 part per million in total solid diet of 1500 g, normally consumed by a 60 kg human subject. The FDA will calculate permissible exposure, when evidence indicates that the residue bioaccumulates in the tissues of target animals.
- A teratology study in a second species when the compound is structurally related to a known teratogen, when the compound has hormonal activity that may affect the fetus or when the compound shows adverse effects in the reproduction/teratology study indicating that the compound may be a teratogen.
- Other specialized testing if necessary to define the biological effect of the compound. Examples of specialized studies include testing for neurotoxicity, for immunotoxicity, for hormonal activity, for toxicity following *in utero* exposure or for toxicity from a “bio-mass” product.

If the testing shows that the sponsored compound is a carcinogen, FDA will apply the “no-residue” requirement of Section 409(c)(3)(A), 512(d)(1)(H) or 706(b)(5)(B) of the Act as operationally defined in 21 CFR subpart E of Part 500. FDA will calculate the concentration of residue giving no significant risk of cancer from the tumor data using a statistical extrapolation procedure. In the absence of information establishing the mechanism of carcinogenesis for a particular chemical, FDA will use a non-threshold, linear-at-low-dose extrapolation procedure that determines the upper limit of the risk ([Gaylor and Kodell, 1980](#); [Farmer \*et al.\*, 1982](#)). In the extrapolation FDA will use the upper 95% confidence limit on the tumor data and a permitted maximum lifetime risk to the test animal of 1 in 1 million.

#### *Acceptable daily intake and safety factors*

For other toxicological endpoints, FDA will calculate the acceptable daily intake (ADI) from the results of the most sensitive study in the most sensitive species. From that study the ADI is the highest dose showing NOEL divided by the appropriate safety factor ([Table 9.2](#)).

#### *Sex steroids*

Although not all sex steroids are demonstrated carcinogens, the evidence supports FDA’s conclusion that all

**TABLE 9.2 CVM: human food safety studies and safety factors**

Type of study	Safety factor
Chronic	100
Reproduction/teratology (100 for a clear indication of maternal toxicity, 1000 for other effects)	100 or 1000
90 days	1000

**TABLE 9.3 CVM: human food safety and endogenous sex steroids**

Sex steroids	Daily production ( $\mu\text{g}$ )	Permitted increased exposure ( $\mu\text{g}$ )
Estradiol	6	0.06
Progesterone	150	1.50
Testosterone	32	0.32

endogenous sex steroids and synthetic compounds with similar biological activity should be regarded as suspect carcinogens, and that the endogenous sex steroids are not genotoxic agents. If these compounds produce an oncogenic response in experimental animals, the mechanism of action is not related to a direct chemical interaction with DNA. Specifically, tumor development is a consequence of hyperproliferation of endocrine-sensitive tissue resulting from persistent overstimulation of the hormonal system.

The safety of endogenous sex steroids and their simple ester derivatives can be assured without additional animal study data. Large quantities of these compounds are produced by *de novo* synthesis in people and food-producing animals. The FDA has concluded that no physiological effect will occur in individuals ingesting animal tissues that contain endogenous steroids equal to 1% or less of that produced daily in the population with the lowest production. In the case of estradiol and progesterone, prepubertal boys synthesize the least; in the case of testosterone, prepubertal girls synthesize the least. The daily production values and the calculated increase permitted above the amount naturally present in untreated target animals are listed in Table 9.3. The product is considered safe within the meaning of the Act, if data acceptable to the FDA demonstrate that under the proposed conditions of use, the residue concentration of the endogenous sex steroid in treated food-producing animals does not exceed the permitted increase at the time of slaughter.

#### *Synthetic sex steroids*

In addition to the standard requirements, FDA recommends the following additional tests:

- A 180-day study in rhesus monkeys or another suitable subhuman primate is required to assess the effect

of the sponsored compound on various parameters including ovulation, menstrual cycle, circulating levels of gonadotropins and sex steroids. The study should establish a dose that gives a no observed hormonal response.

- FDA will also normally use a safety factor of 100 for the study in subhuman primates. If a carcinogenic response is observed in a non-endocrine-sensitive tissue, FDA will determine the dose that will satisfy the “no-residue” requirement of the act using the tumor data from that tissue and a statistical extrapolation procedure.

### **Animal efficacy studies**

Efficacy studies are clinical studies. The purpose of an efficacy study is to evaluate the response of the test article under actual conditions of use. Clinical studies to establish efficacy are also important to the overall safety assessment of the product. GLP regulations do not apply because clinical studies are conducted in a clinical environment under actual conditions of use, rather than in a rigorously controlled laboratory setting. For example, veterinary practitioners may enroll their client’s dogs in a non-steroidal anti-inflammatory study and food-animal producers may participate in a production drug study. In efficacy studies, special care must be exercised in handling animals to avoid undue stress which may alter the response to the drug, greatly affecting the study results. If there is a need to collect samples for laboratory analysis that is unrelated to the collection of efficacy data, all animals are sampled at specified times in order to minimize bias.

The design of the efficacy trial is flexible and depends on the species, breed, drug, class of production animal and data endpoints. In some instances, such as for production drugs, many animals are required per treatment group for the efficacy trial because of variability due to environmental conditions and in the test animals. For typical therapeutic products, the number of subjects required for an animal drug clinical trial is about 5–10% of the number required for an equivalent human drug clinical trial. Additionally, while toxicity is not the objective of these studies, animals are observed periodically (usually daily) for clinical signs and abnormalities. These observations give valuable information for designing additional safety study protocols or reveal information that would appear in the safety information on the product label. Some animals may be necropsied at the end of the study if animals exhibit signs of toxicity. On the other hand, the drug may also be discontinued in an animal exhibiting toxic signs.

Even though the efficacy studies are non-GLP, the test methods and procedures for administering the test article are verified and monitored throughout the study. This ensures that the drug is being delivered to the animals according to the protocol. For example, an oral

drug may be administered with or without food, or the mixing procedure for dispersing a production drug in feed must be periodically validated.

After all requirements have been met, FDA approval of the product allows it to be legally marketed and promoted as a new animal drug. The label must contain the product claim(s), pharmacology, side effects, precautions and warnings. After approval, the drug is monitored through periodic and special industry drug experience reports (DERs) to CVM. These reports include adverse experiences and may result in label changes related to product safety.

### ***Regulatory requirements for reporting animal adverse drug events***

#### *Introduction*

CVM does not evaluate complaints for pesticides and animal vaccines. These complaints should be sent to the Environmental Protection Agency (EPA) or the USDA. The CVM will accept safety information for animal feeds, animal devices, human drugs used in animals and approved animal drugs. Mandatory reporting of safety complaints by the company are only required for approved animal drugs to include medicated feeds. Animal medicated feeds may be mixed incorrectly or given to the wrong species, such as when monensin intended for cattle is fed to horses. Alternately, animal feeds may be contaminated with natural or man-made toxins, such as aflatoxin and polychlorinated biphenyls (PCBs), with the potential for serious consequences in humans and the target species.

Although there are no regulatory requirements for the firm to report post-approval safety information for animal devices, CVM will take regulatory action when necessary. Pre-market approval is not required: the FDA does not require formal pre-market approval for devices used in veterinary medicine (510(k) of the FFDCa). Firms that manufacture radiation emitting devices need to register their products under the radiological health regulations, administered by the Center for Devices and Radiological Health. FDA does have regulatory oversight over veterinary devices and can take appropriate regulatory action if a veterinary device is misbranded, mislabeled or adulterated. It is the responsibility of the manufacturer and/or distributor of these articles to assure that these animal devices are safe, effective and properly labeled.

The Center for Drug Evaluation and Research does not require the pharmaceutical company to report safety complaints from extra-label use of human drugs in animals. CVM will process and evaluate the complaints concerning the extra-label use of human drugs in animals, such as methimazole use for hyperthyroid cats.

#### *Pharmacovigilance*

Pharmacovigilance consists of the means and methods for monitoring and ensuring the safety and efficacy of

marketed medicinal products. (*Note:* For the purpose of this section, the term “pharmaco-” is used to encompass not only drugs, but all types of medicinal products.) Pharmacovigilance is made necessary by the limitations of pre-approval or pre-registration studies for animal medicinal products. Economic and practical considerations limit the number of animals included in safety and efficacy studies. Further, many of the animals utilized during the testing phase consist of experimental animals that are homogeneous in age, breed and genetics. More variation is obtained when the drug is tested in clinical studies, but these types of studies generally have few animals. Thus, while pre-marketing studies may be adequate in demonstrating efficacy and common adverse drug reactions, they generally have limited power to detect less frequently occurring adverse events that may occur when the product is finally utilized under actual conditions of use in the general veterinary community.

Veterinary pharmacovigilance within the federal government is typically based on the receipt of spontaneous reports involving complaints of product performance. Spontaneous refers to reports that are voluntarily submitted by veterinarians, animal producers and animal owners. The reports may be submitted by mail, phone, fax or email. The reports may be originally submitted to either the drug company involved or directly to CVM. Product complaints might involve a suspected animal injury, failure of the product to perform (or ineffectiveness) or a product defect.

The key to understanding the spontaneous AER (adverse event report) reporting process is in recognizing and appreciating the word “suspected.” Any complaint must start with the establishment of an actual AER. The pharmacoepidemiologist understands that any one spontaneously reported AER might be misrepresented, or perhaps not existed at all. A certain level of bias is automatically introduced when the reporter associates the AER with the administration of a specific drug. Lacking evidence that unquestionably documents and supports the AER occurrence, information criteria must be established for accepting an AER into a pharmacovigilance system. This information should include an identifiable reporter, an identifiable animal, an identifiable product and an adequately described adverse event.

In the case of the existence of an actual AER, a reporter lodges a complaint in the form of an AER. The AER is the mechanism through which all relevant aspects of the AE are described. The main goal of the pharmacovigilance program receiving an AER should be to ensure that all needed data elements are accurately and fully described. In many cases, follow-up information may be needed to augment the original AER. Even if the most accurate information is obtained for an AER, the possibility of one or more alternative non-drug-related explanations for the AE occurrence cannot be discounted.

This type of system establishes some level of assurance that the drug under question was “associated” with the reported AER. Strength of association is often determined by utilizing objective-based guidelines termed algorithms. The main strength of the spontaneous reporting system is in detecting the occurrence of drug-related adverse effects that are uncommon and cannot be detected by pre-marketing studies, which generally have low statistical power. Once a trend or suspected adverse reaction is detected, other methods may be used to investigate the suspected AER and determine the most appropriate course of action. For instance, the drug company may be requested to provide more information or to conduct studies investigating the specific issue, or expert opinions may be sought from relevant veterinary specialists. Recommended actions might include labeling changes, the recall of specific batches of product or even the removal of the product from the market.

*FDA/CVM adverse drug event reporting system for approved animal drugs*

The regulations that specifically address the spontaneous reporting obligations of the drug sponsors of FDA-approved animal drugs are contained in “Records and reports concerning experience with new animal drugs for which an approved application is in effect” (21 CFR 514.80). Reporting of AERs is mandatory for the pharmaceutical industry. It is voluntary for veterinarians and consumers.

For industry reporting, the regulations categorize AERs into three categories: significant product defect reports that should be submitted to an FDA District Office within 3 days (21 CFR 514.80(b)(1)); AERs involving unexpected animal injury and unexpected product ineffectiveness that should be submitted within 15 working days to CVM (21 CFR 514.80(b)(2)); and the remaining types of AERs and product defects which should be submitted at periodic intervals to CVM (21 CFR 514.80(a)(4)). All categories of complaints are required to be submitted by the drug sponsor on the OMB-approved Form FDA 1932 (“Veterinary Adverse Drug Reaction, Lack of Effectiveness, and Product Defect Report”).

Significant product defects are those involving either label mix-ups or a significant departure of the product from approved specifications, where the product defect may result in immediate harm to animals. Corrective action is accomplished through the FDA Field Office responsible for the manufacturing site.

AERs requiring 15-day submissions are serious and unexpected (21 CFR 514.3 and 514.80):

- fatal or life threatening;
- require professional intervention;
- causes an abortion, or stillbirth, or infertility, or permanent disability disfigurement;

- unexpected AERs are not on the current label or may be pathophysiologically related to an AER on the label.

Unexpected refers to information that is not contained either on product labeling or as part of the approved FDA application. Regulations further require reporting of unexpected adverse events that are associated with clinical use, studies, investigations or tests, whether or not determined to be attributable to the suspected drug. A key phrase is whether or not it is determined to be attributable to the suspected drug. CVM expects the drug sponsor to submit all AERs rather than only those reports the firm believes are associated with the AER. CVM considers selective report submission (filtering) to introduce a bias that confounds the evaluation of submitted AERs.

All AERS submitted to CVM are evaluated by a staff of veterinarians assigned to this task. All relevant information is extracted from the AERs and entered into the appropriate fields of a relational database, using standard terminology. A six-step algorithm evaluation process is utilized to assign a score that represents the strength of the veterinarian’s opinion that the use of the drug was associated with the adverse clinical sign.

The database is utilized by product manager veterinarians assigned to monitor the safety and efficacy of specific products. In the event that a potential problem is identified, the Monitored Adverse Reaction Committee (MARC) is convened to assist in evaluating information related to the potential problem. The MARC also recommends appropriate regulatory action, in the event the problem is considered significant. AER information is released to the public by means of summary report publication on the CVM website. Additional requests for AER information can be made through the freedom-of-information officer.

AER submission is required only from companies marketing FDA-approved animal drugs. There are no requirements for submitting AERs for human drugs used in animals or unapproved products labeled for animals. CVM will accept reports directly from consumers and veterinarians regarding extra-label use of human drugs and unapproved animal drug products. CVM has limited ability to monitor the performance of these drugs in animals.

Veterinarians are encouraged to report AERs directly to the manufacturer/sponsor. The manufacturer should record the information and send a report of their investigation to CVM. Another reporting option is to call the CVM AER hotline (1-888-FDA-VETS) to report AERs. An FDA veterinarian will return the phone call. The reporter can also either call or write the CVM to obtain a pre-postage-paid reporting form.

AER reporting to CVM has significantly increased over the last decade. During the early 1990s, the CVM

received approximately 1000 AERs each year. CVM received about 33,000 AER reports for the year 2005. Reasons for the increase are numerous, but include the new types of drugs approved for use in companion animals, label information provided for contacting drug companies and the interest of the public in reporting perceived product problems.

#### *The future of global pharmacovigilance reporting*

The USDA and FDA are participants in the construction of a global AER platform. The reporting format for AERs will be standardized but not the causality assessment, evaluation of risk for each AER and the pharmacoepidemiologic approach that may include a mathematical analysis. Standardized evaluation of AERs is impractical because conditions of use for a drug vary from country to country. Spontaneous reporting does not readily lend itself to classical epidemiologic analyses because the numerator (number of animals) is under-reported and the denominator (number of doses) is unknown. Therefore, it is extremely difficult to calculate a true incidence.

Global harmonization of reporting requirements for AERs is no small task. It must be kept in mind that, unlike human AERs, veterinary medicine deals with multiple species which adds more complexity to a complicated process. In addition, reporting requirements differ substantially from country to country because missions, goals, resources, administrative procedures and AER sources vary considerably. The variations reflect the fundamental differences in the worldwide agencies and the laws they administer. The International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products (VICH, 2005) is a trilateral (EU–Japan–United States with two observer countries: Australia and Canada) program aimed at harmonizing technical requirements for animal medicinal product registration to include pre-approval review and post-approval monitoring (International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products). In 1996, at the inception of VICH, one goal was the harmonization of pharmacovigilance reporting requirements: definitions, data elements, electronic submission protocols and medical dictionaries.

Successful efforts of VICH will lead to the timely transmission of AER information between all parties and organizations involved in animal pharmacovigilance. Electronic reporting standards would also be available to consumers and veterinarians who could report directly to the regulatory agency rather than the company. The standardized AER information will be disseminated

worldwide for examination and analysis by all interested parties.

## SECTION II. ENVIRONMENTAL PROTECTION AGENCY

### Creation of the EPA

During the 1960s activists became increasingly effective in focusing attention on environmental and public health issues. Rachael Carson's book, *Silent Spring* (1962), provided a worldwide view of the effects of indiscriminate use of pesticides. By 1969, the word "ecology" had become part of American culture. Under criticism that his environmental committees were largely ceremonial bodies, President Nixon appointed a White House Committee in December of 1969 to consider whether there should be a separate environmental agency. About the same time, Congress sent the National Environmental Policy Act (NEPA) to the president, which he signed on January 1, 1970.

It was against the background of environmental activism that Reorganization Plan No. 3 was sent to Congress by the Nixon Administration. Under Reorganization Plan No. 3, the EPA was formed in 1970 to establish and enforce environmental protection standards; to conduct environmental research; to provide assistance to other agencies in combating environmental pollution; and to assist in developing and recommending new policies for environmental protection. The regulatory activities for environmental protection were consolidated from 15 components of five executive departments and independent agencies into a single agency, the EPA. Certain pesticide regulatory functions were transferred from FDA and USDA to EPA. The enactment of major new environmental laws and important amendments since 1970 have expanded and refined the role of the EPA (Table 9.4).

The EPA is organized into major Offices headed by assistant EPA administrators which develop and implement EPA's policies and programs. For instance, the Office of Prevention, Pesticides and Toxic Substances (OPPTS) develops national strategies for toxic substance control and promotes pollution prevention and the public's right to know about chemical risks. A component Office, the Office of Pesticide Programs (OPP), regulates the use of all pesticides in the United States and establishes maximum levels for pesticide residues in food. The EPA also has geographically organized regions. Each EPA Regional Office is responsible, within selected states, for the execution of the Agency's programs, considering regional needs

**TABLE 9.4 Major statutes that form the basis for the programs of the EPA**

Statute or law	Description
Federal Food, Drug, and Cosmetic Act, Delaney Clause (1958)	FFDCA prohibited any man-made chemical in food that caused cancer in any animal, including man.
National Environmental Policy Act (1969)	NEPA is the basic national charter for protection of the environment.
Clean Air Act (1970)	CAA is the comprehensive federal law that sets standards regulates air emissions from area, stationary and mobile sources.
Occupational Safety and Health Act (1970)	OSHA ensures worker and workplace safety from hazards, such as exposure to toxic chemicals, excessive noise levels, mechanical dangers, heat or cold stress, or unsanitary conditions.
Federal Insecticide, Fungicide, and Rodenticide Act (1972)	FIFRA provided federal control of pesticide distribution, sale and use and required users (farmers, utility companies, and others) to register when purchasing pesticides.
Endangered Species Act (1973)	ESA provides a program for the conservation of threatened and endangered plants and animals and the habitats in which they are found.
Safe Drinking Water Act (1974)	SDWA was established to protect the quality of drinking water in the United States.
Resource Conservation and Recovery Act (1976)	RCRA gave EPA the authority to control hazardous waste during the generation, transportation, treatment, storage, and disposal of hazardous waste.
Toxic Substances Control Act (1976)	TSCA gave EPA the ability to track about 75,000 industrial chemicals produced or imported into the United States.
Clean Water Act (1977)	CWA gave EPA the authority to set effluent standards on an industry basis (technology based) and continued the requirements to set water quality standards for all contaminants in surface waters.
Comprehensive Environmental Response Compensation and Liability Act (1980)	CERCLA created a tax on the chemical and petroleum industries and provided broad federal authority to cleanup abandoned hazardous waste sites (Superfund).
Emergency Planning and Community Right-to-Know	EPCRA was enacted by Congress as the national legislation on Act (1986) community safety.
Superfund Amendments and Reauthorization Act (1986)	SARA amended CERCLA and reflected EPA's experience in administering the complex Superfund program.
Pollution Prevention Act (1990)	PPA encouraged industry to control toxic emissions by using cost-effective changes in production.
Oil Pollution Act (1990)	OPA streamlined and strengthened EPA's ability to prevent and respond to catastrophic oil spills through a tax on oil.
Food Quality Protection Act (1996)	FQPA amended FIFRA and FFDCA.

and the implementation of federal environmental laws (USEPA, 2000b).

### **Pesticides and the federal insecticide, fungicide and rodenticide act**

The Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) has a major impact on the practice of veterinary medicine because it provides EPA the authority to regulate pesticide use in animals. Under FIFRA the term pesticide includes products such as insecticides, fungicides, rodenticides, insect repellants, weed killers, anti-microbials and swimming pool chemicals. Pesticides are intended to prevent, destroy, repel or reduce pests of any sort. If a pesticide can be used with "reasonable certainty of no harm," it is granted a "registration" that permits its sale and use according to requirements set by EPA to protect human health and the environment. During

its evaluation of a proposed pesticide the EPA considers the toxicity of the pesticide, the quantity and frequency of pesticide application and the amount of pesticide that remains on the food by the time it is marketed.

The FIFRA was enacted in 1947 as a consumer protection statute to regulate the manufacture, sale, distribution and use of pesticides. The USDA administered FIFRA. Pesticide registration was required before marketing in interstate commerce, and the pesticide product had to bear a label with the manufacturer's name and address, name brand and trademark of the product, net contents, ingredient list, warning statements to prevent injury, and directions for use. Subsequent amendments added more product classes including nematicides, plant regulators, defoliants and desiccants (1959); and a requirement that all pesticide labels contain a Federal Registration Number and safety information words such as "warning," "danger," "caution" and "keep out of reach of children" (1964).

In 1970, authority for FIFRA was transferred from the USDA to the newly created EPA. Another amendment in 1972 provided the EPA with authority to regulate pesticides to prevent unreasonable adverse effects on the environment. The 1972 amendment changes included requirements to follow the label, heavy fines for violations, classification of pesticides as “restricted use” or “general use,” state certification, manufacturer registration and inspection by EPA, and scientific evidence that the product is effective and safe for humans, crops and animals. Subsequent clarifying amendments provided for significant changes to improve the registration process including generic standards for the active ingredient rather than for each formulated product, re-registration of all products registered prior to 1975, conditional registration where efficacy data may be waived, state enforcement authority and defined the phrase: “to use any registered pesticide in a manner inconsistent with its labeling.” In 1988, the EPA was required to re-register existing pesticides that were originally registered before current scientific and regulatory standards were formally established. The Food Quality Protection Act (FQPA) of 1996 is the most recent significant amendment to FIFRA.

## Pesticide residues in foods

When pesticides are used in producing food, they may remain in small amounts called residues. To protect the public from potentially harmful effects caused by pesticide residues on food, the EPA regulates the amount of each pesticide that may remain on or in each food. EPA regulates pesticides under two major federal statutes. Under the FIFRA, EPA registers pesticides for use in the United States and prescribes labeling and other regulatory requirements to prevent unreasonable adverse effects on health or the environment. Under the FFDCA, EPA establishes tolerances (maximum legally permissible levels) for pesticide residues in food. Tolerances are established as part of the pre-market registration process. Exceeding the tolerance initiates enforcement actions where the commodity may be subject to seizure. Tolerance limits apply to both domestic and imported food. Some foods do not require tolerances because the exposure and toxicity data show that the food is safe when the pesticide is used according to the directions on the label.

Several other government agencies enforce EPA’s pesticide tolerances in food. The FDA tests food produced in the United States and imported food. State agencies also test food produced in the United States. The USDA tests milk, meat and eggs. The USDA and FDA have programs designed to develop statistically valid information on pesticide residues in foods. This information is provided to EPA for use in risk assessments for pesticides.

When the USDA detects violations of tolerances in their data collection program, they notify FDA.

EPA has responded to both large and small environmental disasters during the past 30 years. Less visible but just as important is EPA’s present effort to reassess all the pesticide and other ingredient tolerances and exemptions that were in effect as of 1996 when the FQPA of 1996 was passed. It amended both the FIFRA and the FFDCA. These amendments changed the way EPA regulates pesticide residues. Examples of FQPA changes include a single residue safety standard of “a reasonable certainty of no harm”; requirement for an explicit determination that pesticide tolerances are safe for children (includes an additional safety factor); limits consideration of benefits when setting tolerances to non-threshold (such as carcinogenic) effects; requirement to review existing pesticide tolerances within 10 years; authorization to require new data, including potential endocrine effects; imposition of civil penalties; and expedited review of safer pesticides.

## EPA companion animal safety testing

Companion animal safety studies for EPA-registered pesticides apply only to dogs and cats because of widespread use of these external products for pests (USEPA, 1998). The companion animal safety study is required for pesticide registration. Companion animal safety studies for pesticide formulations for the treatment of external pests are intended to demonstrate that an adequate margin of safety exists with overuse or misuse (40 CFR Section 792 and 40 CFR 160, GLP Standards). Data from companion animal safety studies for pesticides serve as a basis for product labeling. The study can be compared to an acute dermal toxicity study, and is limited because an NOEL is not required. External pesticide products include collars, sprays, dips, shampoos and spot treatments.

The design of a companion animal safety study should reflect the product label: method of administration, species and age group, and frequency of application. The criteria for use of the product should be used in the study. A control group should receive a concurrent vehicle at the 5× level. The vehicle should contain the inert ingredients at the maximum levels that would appear in the 5× formulation. Negative (untreated) controls may occasionally be employed to determine whether adverse effects are due to the inert ingredients in a formulation. The test formulation is applied to several groups of (six/sex) experimental animals at the label dose and multiples of this dose (3× and 5×). For exaggerated doses (3× and 5×), products specifically prepared for this type of study that contain higher concentrations of the active ingredient are preferred. If the drug cannot be formulated at the 3× or 5× concentration, due to volume constraints, multiple treatments at frequent intervals may be

necessary. If the high-dose level (at least 5×) produces no evidence of drug-related toxicity, a full study (three dose levels) may not be necessary. Multiple pesticides formulated into a single product may also be evaluated. Depending on the severity of clinical signs of toxicity, products with less than 5× margin of safety may be considered for registration. The route of administration of these product studies should be topical. The skin or hair should not be prepared in any manner unless such directions appear on the label. If the product label recommends several treatments, multiple treatments at frequent intervals are included in the study design based on label claims and instructions for use.

The species recommended for treatment on the product label is included in the study. Studies are performed on representative classes of healthy dogs and cats by size, weight, sex and age based on label claims. For instance, if only adults over 6 months of age are the label population of animals to receive treatment, only adults are enrolled in the study. If the product is registered for puppies and kittens, the label should state a minimum age for this group and this class should be included in the study. An equal number of animals per sex are used at each dosage level. Animals are appropriately examined and prepared during the acclimation period.

Clinical observations are conducted at hourly intervals for at least 4h after the last treatment, and twice daily for the duration of the study. If adverse reactions are observed, the observation period on the day of treatment is extended to a time at which no toxic signs are observed. Observations should include all systems. Special attention is directed to observations of central nervous system signs of seizures, tremors and salivation; and gastrointestinal signs of vomiting and diarrhea. Observations and measurements are reported for a minimum of 14 days post-treatment and longer if appropriate. Various samples and measurements are collected throughout the study. Individual body weights and food consumption are measured during the acclimation and periodically during the study. Animals that die or are euthanized in a moribund state are subjected to a gross necropsy and abnormal tissues are examined histopathologically to determine the cause of death. Routine post-study necropsy is not required. Clinical pathology samples including red cell cholinesterases, when appropriate, are assessed prior to treatment, 24h post-treatment, and on day 7 of treatment.

## Chronic toxicity testing: pesticides in animal-derived food

### Introduction

The USEPA requires a variety of toxicity testing prior to registration of pesticides. The 870 Series Final Guidelines

describe study protocols that meet testing requirements of the FIFRA and the Toxic Substances Control Act (TSCA): Reproduction and Fertility (870.3800) and Combined Chronic Toxicity/Carcinogenicity (870.4300) (USEPA, 1998, 2000a).

### Reproduction toxicity testing

The two-generation reproduction study provides information on the effects of a test substance on the male and female reproductive systems. The study should be conducted in accordance with the GLP Standards stipulated in 40 CFR Part 160 (FIFRA) and 40 CFR Part 792 (TSCA). The test substance is administered to parental (P) animals prior to and during their mating, during the resultant pregnancies and through the weaning of their F1 offspring. The substance is then administered to selected offspring during their growth into adulthood, mating and production, and weaning of a subsequent generation. The rat is the most commonly used species for testing. Each control group should contain a sufficient number of mating pairs to yield approximately 20 pregnant females. Each test group should contain a similar number of mating pairs. At least three dose levels and a concurrent control should be used. The dose levels should be spaced to produce a gradation of toxic effects. The highest dose should be chosen to induce some reproductive and/or systemic toxicity but not death or severe suffering. The intermediate-dose levels should produce minimal observable toxic effects. The lowest-dose level should not produce any evidence of either systemic or reproductive toxicity. The highest dose tested should not exceed 1000mg/kg/day (or 20,000ppm in the diet), unless potential human exposure data indicate the need for higher doses. A concurrent control group should be used. The test substance is usually administered by the oral route (diet, drinking water or gavage). The animals should be dosed with the test substance on a daily basis. Daily dosing of the parental males and females should begin when they are 5–9 weeks old, and that of the offspring should begin at weaning. Daily dosing should begin at least 10 weeks before the mating period and continue until termination.

The endpoints measured should provide data regarding the performance of the male and female reproductive systems including gonadal function, the estrous cycle, mating behavior, conception, gestation, parturition, lactation and weaning, and on the growth and development of the offspring. The study may also provide information about the effects of the test substance on neonatal morbidity, mortality, target organs in the offspring and preliminary data on prenatal and postnatal developmental toxicity, and serve as a guide for subsequent tests. Additionally, since the study design includes *in utero* as well as postnatal exposure, it provides the

opportunity to examine the susceptibility of the mature/neonatal animal. For further information on functional deficiencies and developmental effects, additional study segments can be incorporated into the protocol, utilizing the guidelines for developmental toxicity or developmental neurotoxicity (USEPA, 1996).

#### **Combined chronic toxicity/carcinogenicity testing**

The objective of the combined chronic toxicity/carcinogenicity study is to determine the effects of a substance in a mammalian species following prolonged and repeated exposure. If chronic/carcinogenic effects are detected in the first mammalian species, usually the rat, further long-term studies may be conducted in another species, usually the dog. The design and conduct should allow for the detection of neoplastic effects and a determination of the carcinogenic potential as well as general toxicity, including neurological, physiological, biochemical and hematological effects and exposure-related morphological (pathology) effects.

Preliminary studies providing data on acute, subchronic and metabolic responses should be conducted. The rate of exposure is generally oral, dermal or inhalation. For the combined chronic toxicity/carcinogenicity study, the rat is the species of choice for oral and inhalation studies, whereas the mouse is species of choice for the dermal route. The choice of the route of administration depends on the physical and chemical characteristics of the test substance and the product exposure in humans. The duration of studies should be at least 18 months for mice and hamsters and 24 months for rats. The following general requirements apply to all combined chronic toxicity/carcinogenicity studies regardless of the route of administration. Testing should be started with young healthy animals as soon as possible after weaning and acclimatization, but no later than 8 weeks of age. At commencement of the study, the weight variation of animals used should be within 20% of the mean weight for each sex. At least 100 rodents (50 males and 50 females) should be allotted randomly to each dose level and concurrent control group. At least 20 additional rodents (10 males and 10 females) should be used for satellite dose groups and the satellite control group. The purpose of the satellite group is to allow for the evaluation of chronic toxicity after 12 months of exposure to the test substance. The number of animals in any group should not fall below 50% during the course of the study at 15 months in mice and 18 months in rats, so that a meaningful and valid interpretation of negative results can be achieved. Survival in any group should not fall below 25% at 18 months in mice and 24 months in rats.

#### **Organization for Economic Cooperation and Development**

The Organization for Economic Cooperation and Development (OECD) carried forward recommendations

of an international expert group and questioned the value of clinical pathology findings, including hematology and clinical chemistry, beyond 12 months in chronic and combined chronic/carcinogenicity studies (Weingand *et al.*, 1996). As a result, hematology and clinical chemistry measures beyond the 12-month period have been eliminated. The observational and functional tests on the nervous system and behavior have also been revised per OECD. Recently, the requirement for the 6-month long-term studies in the dog has been modified. Long-term studies (6 months or longer) in the dog will not be conducted unless warranted by findings in long-term rat studies.

#### **EPA adverse effects information reporting**

At EPA, regulatory responsibilities for pesticides are centralized at the OPP. Regulatory authority is derived from Section 6(a)(2) of the FIFRA. The regulations that specifically address reporting of adverse effects of pesticides are contained in Reporting Requirements for Risk/Benefit Information (40 CFR Section 159). Reporting of AERs is mandatory for industry.

Pesticides are broadly defined to include insecticides, herbicides, fungicides and various other substances that are not animal drugs used to control pests. A pesticide is also any substance or mixture of substances intended for use as a plant regulator, defoliant or desiccant. The EPA collects information on pesticide use, whether intended or unintended. Adverse effects information may include information on human or animal injury, plant injury or environmental contamination. All adverse effects information is accepted regardless of the registered label use of the product.

Specific industry reporting requirements for adverse effects information depends on the category of the information. Reports of human death should be submitted within 15 calendar days as an individual report. A variety of other information, including suspected product defects, human epidemiology and exposure studies, and pest resistance reports should be submitted within 30 calendar days as individual reports. Reports involving major and moderate human injury, major injury to plants and wildlife, water contamination and public health product ineffectiveness should be submitted after a 1-month accumulation as individual reports.

Animal reports receive less priority than human reports. Reports involving any type of domestic animal injury, and some minor types of human, plant and wildlife injury, should be reported within 2 months, after a 3-month accumulation of reports. The information may be submitted in an aggregate format. An aggregate report for a specific time period includes a count of domestic injuries within categories of assessed seriousness. Information concerning the specific details of each

individual AER is not included in an aggregate. The EPA, however, may request additional information for any AERs that involved the death of an animal.

The EPA/OPP gathers adverse effects information from other sources. Information may result from complaints made directly to the EPA. This AER information is entered into the EPA Incident Database. Information may also be obtained through the National Pesticide Communications Network, based at Oregon State University, and other sources. Much of this information may be entered into the EPA Incident Data System. Some aggregate reports may also be entered into the system.

Various product divisions within OPP review the AER information. A complete review of product-related information is performed when it is being considered for re-registration. A Special Review may be set in motion when EPA has reason to believe that the use of a pesticide may result in unreasonable adverse effects, including acute toxicity to domestic animals. Subsequent regulatory actions may range from removal of the product from the market to changes in permitted uses.

Since the EPA/OPP regulates all pesticides, jurisdictional AER issues resulting from extra-label use are not a consideration. Further, the mission of OPP is to monitor the safety of pesticides in humans and animals regardless of the intended use. Evaluation of domestic animal AERs involving pesticides labeled for therapeutic use on animals is given the same attention as a pesticide labeled for use on plants. Intended use is more likely to affect what regulatory actions may be subsequently taken to improve the overall safety of product use.

## SECTION III. U.S. DEPARTMENT OF AGRICULTURE

### Regulatory authority and mission

The authority for regulating veterinary biologics in the United States is provided in the Virus–Serum–Toxin Act (VSTA), enacted in 1913 and amended in 1985 ([USDA APHIS Center for Veterinary Biologics, 2005a](#)). It requires, with some exceptions, that all veterinary biologics be licensed. The Licensing and Policy Development (LPD) unit in the Center for Veterinary Biologics (CVB), Veterinary Services, Animal and Plant Health Inspection Service (APHIS), and U.S. Department of Agriculture (USDA) enforces the VSTA. The Act authorizes the Secretary of USDA to prescribe regulations governing the preparation and marketing of veterinary biologics shipped into, within or from the United States. The VSTA makes it unlawful to sell worthless, contaminated, dangerous or harmful veterinary biologics or to ship veterinary biologics to or from the United States unless they are prepared in a licensed

establishment in compliance with USDA regulations. It requires the issuance of a permit by USDA prior to the importation of a veterinary biological product and gives the department the authority to test veterinary biological products prior to importation. In case of violation, the Act permits USDA to remove or suspend establishment and/or product licenses and permits. It also gives authority for detention, seizure and condemnation of products and injunctions against products or establishments.

### Definition and functions

The regulations in 9 CFR 101.2(w) define veterinary biological products to be all viruses, serums, toxins and analogous products of natural or synthetic origin that are intended for use in the diagnosis, treatment or prevention of diseases of animals. The products include diagnostics, antitoxins, vaccines, live or killed microorganisms and their antigenic or immunizing components. The LPD reviews license applications for production facilities and biological products and for importation. It reviews production methods, labels and supporting data involved in the licensing and permit process and issues licenses and permits. An exemption from this licensing provision is given for products prepared by: (1) a person solely for administration to that person's own animals; (2) a veterinarian for use in his or her own licensed practice under a veterinarian–client–patient relationship; and (3) a person operating a state licensed facility solely for distribution of product within the state of production in a state that has the state regulatory USDA-approved control program for veterinary biologics. The VSTA provides for the issuance of conditional or special licenses for products in order to meet an emergency condition.

A proposed rule to amend the VSTA (9 CFR Parts 101 and 116) was published in the [Federal Register](#) on August 17, 2005 (Vol. 70, No. 158, p. 48325) ([USDA APHIS Guidance Documents, 2005b](#)). For newly licensed products, the proposed rule requires veterinary biologics licensees to record specific information concerning adverse events associated with the use of biological products that they produce or distribute and to compile and submit those records in a summary report to the APHIS every 12 months for products licensed for one year or more. A summary report would have to be submitted at 6-month intervals during the first year of the product license and at 12-month intervals thereafter. The VSTA did not explicitly require licensees to maintain records of adverse events associated with the use of veterinary biologics, nor do the regulations in Part 116.5 provide specific guidance in determining whether an adverse event should be considered an indication that raises questions regarding the purity, safety, potency, efficacy, preparation, testing or distribution of biologics.

Adverse event and AER are defined as follows:

- Any observation in animals, whether or not the cause of the event is known, that is unfavorable and unintended and that occurs after any use (on or off label) of a biological product.
- For products administered to animals, this would include events related to a suspected lack of expected efficacy.
- AER: as a communication concerning the occurrence of an adverse event from an identifiable first-hand reporter that includes at least the following information: an identifiable reporter; an identifiable animal; an identifiable biological product; and one or more adverse events.

#### *Animal immunobiologic vigilance program*

Regulation of animal immunobiologics is centralized within the APHIS and CVB. Regulatory authority is derived from the VSTA. Animal immunobiologics modulate the immune system for the prevention, treatment or diagnosis of disease in animals. Animal immunobiologics typically include vaccines, toxoids and serum derivatives, which may be used in diagnostic test kits.

Immunobiologic vigilance (or vaccinovigilance) may in some respects be more complicated than monitoring the safety of animal drugs, or even therapeutic animal pesticides. Vaccines are generally utilized for the prevention of disease. The real or perceived failure of a vaccine to perform may be dependent on a number of factors and difficult to assess. Suspected vaccine failure in individuals is particularly difficult to assess. Further, assessing AERs involving adverse events that are manifested some time after vaccine administration can be complicated. In addition to the “active ingredient”, vaccines can include other ingredients, such as preservatives, stabilizers and adjuvants, which can affect the product performance. Vaccinovigilance is a particularly challenging discipline that may require substantially more information from formal studies in order to verify suspected problems.

Until the proposed rule is finalized to amend the VSTA, USDA currently has no regulations that require the immunobiologic industry to routinely submit AERs to CVB. Since the immunobiologic industry does not submit AERs, the CVB has limited ability to monitor AERs involving animal safety. USDA may at times request companies to voluntarily submit AERs that are related to a particular safety issue. Although, the USDA does not presently mandate specific AER record keeping practices, the USDA does have the ability to conduct investigations at the immunobiologic manufacturing site.

At present, modest levels of CVB resources are allocated to direct vaccinovigilance activities. However, CVB

can direct resources, as needed, to safety issues. While regulatory actions may be more likely to result in the removal of the registered product from the market, other actions may include manufacturing changes or label revisions.

#### **Animal care and welfare requirements**

Researchers who conduct studies funded by the federal government are subject to a number of requirements imposed by various federal agencies. The Animal Welfare Act (AWA) is administered by the USDA APHIS Animal Care Program ([USDA APHIS Animal Care Program Publications, 2000](#)). It applies specifically to dogs, cats and a number of other listed species as well as to any other warm-blooded animals designated by the Secretary. It requires covered facilities to register and comply with AWA regulations. Examples of types of requirements established to implement AWA include living space, lighting, heating, ventilation, drainage, transportation, feeding and watering, and veterinary care. It establishes the requirement for an Institutional Animal Care and Use Committee, which must include a veterinarian and an external member. This committee reviews the program, inspects the facility periodically and reviews protocols for research conducted within the facility. It does not apply to animal agriculture or non-research horses. It does apply to dealers and exhibitors. Federal agencies such as National Institutes of Health (NIH) may impose additional requirements.

As a practical approach to ensuring that their programs and facilities meet these requirements, many organizations participate in the Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC) International's accreditation process ([Association for Assessment and Accreditation of Laboratory Animal Care, 2005](#)). AAALAC was founded in 1965 to address laboratory animal welfare issues. AAALAC International is a non-regulatory, non-profit corporation. Its mission is to promote high standards for animal care, use and welfare, and enhance life sciences research and education through its accreditation process.

## **SECTION IV. DRUG ENFORCEMENT ADMINISTRATION**

### **Mission and public health impact**

Illegal drug use is a widespread problem in the United States. In 1998, an estimated 13.6 million Americans used an illicit drug at least once during the 30 days prior to

being interviewed. During the same period, nearly 1 in 10 youths aged 12–17 years was an illicit drug user, and 130,000 were current users of heroin. The Drug Enforcement Administration (DEA) was established on July 1, 1973. Its mission is to enforce the controlled substances laws and regulations of the United States and to bring to the criminal justice system, or any other competent jurisdiction, those organizations and principal members of organizations who are involved in the growing, manufacture, or distribution of controlled substances in the United States.

### Illicit veterinary drugs of public health concern

Approved veterinary scheduled drugs, which are illicitly used in humans, include boldenone (Equipoise), ketamine, stanozolol (Winstrol) and trenbolone (Finajet). Veterinary products containing anabolic steroids that are exclusively intended for administration through implants to cattle or other non-human species and which have been approved by the CVM, US FDA are excluded from all schedules (Drug Enforcement Agency: 21 CFR Parts 1300–1316, [List of Scheduling Actions and Controlled Substances, 1999b](#); [Drugs of Abuse, 1997](#)).

Ketamine hydrochloride, known as “special k” and “k,” is a general anesthetic for human and veterinary use. Ketamine produces effects similar to pentachlorophenol (PCP) with the visual effects of lysergic acid diethylamide (LSD). Ketamine sold on the streets comes from diverted legitimate supplies, primarily veterinary clinics. Its appearance is similar to that of pharmaceutical grade cocaine, and it is snorted, placed in alcoholic beverages or smoked in combination with marijuana. The incidence of ketamine abuse is increasing. Ketamine was placed in Schedule III of the Controlled Substances Act (CSA) in August 1999 (Drug Enforcement Agency: 21 CFR Parts 1300–1316, [Schedules of Controlled Substances, 1999a](#)).

Concerns over a growing illicit market and prevalence of abuse combined with the possibility of harmful long-term effects of steroid use led Congress in 1991 to place anabolic steroids into Schedule III of the CSA. The CSA defines anabolic steroids as any drug or hormonal substance chemically and pharmacologically related to testosterone (other than estrogens, progestins and corticosteroids) that promotes muscle growth. Most illicit anabolic steroids are sold at gyms, competitions and through mail operations. For the most part, these substances are smuggled into this country. Those commonly encountered on the illicit market include boldenone (Equipoise), ethlestrenol (Maxibolin), fluoxymesterone (Halotestin), methandriol, methandrostenolone (Dianabol), methyltestosterone, nandrolone (Durabolin, DecaDurabolin), oxandrolone (Anavar), oxymetholone (Anadrol), stanozolol (Winstrol), testosterone

and trenbolone (Finajet). Physical side effects include elevated blood pressure and cholesterol levels, severe acne, premature balding, reduced sexual function and testicular atrophy. In males, abnormal breast development (gynecomastia) can occur. In females, anabolic steroids have a masculinizing effect, resulting in more body hair, a deeper voice, smaller breasts and fewer menstrual cycles. Several of these effects are irreversible. In adolescents, abuse of these agents may prematurely stop the lengthening of bones, resulting in stunted growth (Drug Enforcement Agency: 21 CFR Parts 1300–1316, [List of Scheduling Actions and Controlled Substances, 1999b](#)).

### DEA regulatory requirements for veterinarians

Federal DEA regulations are contained in 21CFR 1300 and 1316 ([U.S. Department of Justice, 2005](#)). Clinicians who are authorized to prescribe controlled substances may do so for legitimate medical purposes in the context of a valid veterinary–client–patient relationship. Under these regulations the prescribing practitioner is held responsible in case the prescription does not conform to the regulations for records and reports (21 CFR 1304), submitting proper ordering forms (21 CFR 1305) and for meeting the requirements for prescriptions (21 CFR 1306 (1)). Requirements for prescribing Schedule II drugs are much more stringent than those for Schedules III, IV and V. For example, an oral order or refilling of the prescription for Schedule II drugs is prohibited under the CSA. DEA has divisional offices in various regions, including Atlanta, Boston, Chicago, Dallas, Denver, Detroit, El Paso, Houston and Los Angeles. In addition, each division has several district offices.

## SECTION V. OCCUPATIONAL SAFETY AND HEALTH ADMINISTRATION

### Organization and mission

Harmful chemical compounds in the form of vapors, fumes, mists, gases, liquids and solids are encountered in the workplace by inhalation, absorption (through direct skin contact), or to a lesser extent by ingestion. Airborne chemical hazards have great occupational health significance. The degree of worker risk from exposure to any given substance depends on the nature and potency of the chemicals’ toxic effects and the duration and intensity of exposure ([Occupational Safety and Health Administration, Informational Booklet on Industrial Hygiene, 2005c](#)).

In 1970 Congress passed the Occupational Safety and Health Act to assure so far as possible every worker

in the nation safe and healthful working conditions ([Occupational Safety and Health Administration, the Occupational Safety and Health Act of 1970, 2005a](#)). The Act requires employers to maintain a safe workplace and created the Occupational Safety and Health Administration (OSHA). This agency's mandate includes regulatory responsibility for establishing mandatory occupational exposure standards, as well as related research, training and education and enforcement. OSHA is part of the Department of Labor and is headed by the Assistant Secretary of Labor for Occupational Safety and Health. Major OSHA programs are administered through Directorates such as the Directorate for Safety Standards Programs which provides workplace standards and regulations to ensure safe working conditions.

### *Offices and district offices*

Under the Act many states have OSHA-approved occupational safety and health programs which function *in lieu* of OSHA programs or standards. OSHA has broad workplace safety responsibilities which pertain to physical hazards such as electromagnetic radiation, temperature, noise and vibration; ergonomic hazards such as repeated motions or heavy lifting; and biological hazards including bacterial and viral pathogens, in addition to the chemical hazards that are the primary subject of this section. The Act also established the National Institute for Occupational Safety and Health (NIOSH) within the DHHS. NIOSH is authorized to develop and establish recommended occupational safety and health standards by conducting research and experimental programs for the development of new and improved occupational safety and health standards.

### **Exposure limits**

OSHA limits occupational exposure to hazardous chemicals by establishing exposure limits and directing changes in employer work processes or equipment, or when that is not feasible requiring personal protective equipment. Unlike drugs, biologics, pesticides or food additives, industry does not need to provide evidence of safety, or obtain an approval prior to manufacturing and marketing new products which may entail occupational exposure to hazardous chemicals. Thus, exposure limits may be adopted after the chemical has entered the occupational environment. The Act specifies that for regulating toxic chemicals OSHA must adopt standards which most adequately assure, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or physical capability. Thus, some consideration must be given to the issue of technological achievability for industry in promulgating standards.

OSHA standards are called permissible exposure limits (PELs). They are legal standards that may not be exceeded. PELs have been controversial and susceptible to successful legal challenges. Thus, many chemicals do not have PELs. In the absence of OSHA PELs employers utilize recommended occupational exposure limits established by acknowledged sources in order to meet OSHA's requirements for worker safety. NIOSH has recommended exposure limits (RELs). The American Conference of Governmental Industrial Hygienists Threshold Limit Values (TLVs) for Chemical Substances and Physical Agents in the Work Environment are very widely utilized ([National Oceanographic and Atmospheric Administration, 1998](#)). TLVs refer to airborne concentrations of substances and represent conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse health effects. There are three categories of occupational exposure limits:

- 1 *Time-weighted average (TWA)*: The TWA concentration for a conventional 8-h workday and 40-h workweek, to which it is believed that nearly all workers may be repeatedly exposed, day after day, without adverse effect.
- 2 *Short-term exposure limit (STEL)*: The concentration to which it is believed that workers can be exposed for a short period of time without suffering from irritation, tissue damage or narcosis, it is not a separate exposure limit but supplemental to the TWA and limited to a 15-min TWA.
- 3 *Ceiling*: The concentration that should not be exceeded during any part of the working exposure ([The American Conference of Governmental Industrial Hygienists, 2005](#)).

The OSHA Hazard Communication Standard (29 CFR 1910.1200), also called the Right-to-Know Law, ensures that the hazards of all chemicals are evaluated and the information concerning their hazards is transmitted to employers and employees. It requires chemical manufacturers and importers to obtain or develop a material safety data sheet (MSDS) for each hazardous chemical they produce or import. Distributors are responsible to insure that their customers are provided a copy of these MSDSs. An MSDS must contain information describing the physical and chemical properties, health hazards, routes of exposure, precautions for safe handling and use, emergency procedures and control measures. The MSDS has become a well-established document for disseminating health and safety information about chemical products ([Occupational Safety and Health Administration, Technical Center Brochure, 2005b](#)). The NIOSH Pocket Guide to Chemical Hazards is another useful document for health and safety information

about hazardous chemicals ([National Institute for Occupational Safety and Health, 1997](#)).

## SECTION VI. STATUTES, REGULATIONS AND GUIDELINES

The three federal agencies (FDA, EPA and USDA), which are responsible for regulating animal health products, all maintain surveillance programs for monitoring products after they are marketed. The laws, which provide regulatory authority, and thus the regulatory goals, regulations and approach by these three agencies, are different. By extension, the pharmacovigilance programs utilized for monitoring the safety and effectiveness of marketed animal medicinal products are different. Thus, they have some common and some different statutes, regulations and guidelines.

### Notice and comment rulemaking procedures and access to agency records

Statutes are legislation passed by Congress and signed by the President. They are the laws that provide the authority for regulatory agencies to operate. Regulations are basic tools for achieving a regulatory agency's goals, such as consumer or environmental protection. Regulations inform the affected industries and the public of statutory requirements and the agency's procedures. Regulations interpret the law and spell out the details needed to implement the general provisions in the statutes. Regulations also describe the product approval process for many individual products or set forth required standards of product composition or performance.

Change is constant and agencies must issue new regulations and amend or revoke old ones. All regulations must be authorized by statute, and the rulemaking procedures must conform to requirements of the Administrative Procedures Act which applies to all executive branch departments and agencies of the federal government. The administrative process for establishing regulations used is referred to as "Notice and Comment Rulemaking."

New and amended regulations and other notices are disseminated by publication in the [Federal Register](#) which is issued daily by the Federal Government ([Federal Register](#)). Regulations are codified in the [Code of Federal Regulations](#) (CFR) which is updated annually. Preparing and issuing a regulation is a complex and lengthy process because agencies must be sure any new rule is needed and well conceived. Stakeholders such

as affected industry and consumers generally must be given an opportunity to participate through the notice and comment rulemaking process. Ordinarily, this is done by publishing in the [Federal Register](#) a notice of proposed rulemaking and inviting comments, within a specified time frame, typically 60 or 90 days. In appropriate cases public hearings are also held. The written and public hearing comments then must be reasonably responded to before issuing a final regulation. After reviewing all comments an agency publishes the final rule in the [Federal Register](#) and announces the effective date of the regulation. The regulation then becomes part of the CFR.

Guidelines establish practices of general applicability and do not include decisions or advice on specific situations. Guidelines are not legal requirements, but may be relied on with the assurance that it is an acceptable procedure or standard. A guideline represents the formal position of the agency on a matter and obligates the agency to follow it until it is amended or revoked. The guideline development process is similar to the regulation publication process. Draft guideline availability and request for comment is typically announced in the [Federal Register](#) and comments are considered when developing final guidelines.

### Freedom of information and public access to regulatory agency records

The Freedom of Information Act (FOIA) went into effect in 1967. It provides access to information in government files and requires that each government agency publishes descriptions of its operations and procedures. Each agency must also make available opinions, orders and statements of public policy that affect the public. Any person can obtain information through an FOIA request. Certain types of information are not available under FOIA. For example, national security-related trade secrets and commercial information and personnel and medical files are exempt. Agencies are given a certain period of time to process requests, typically within 20 days of receipt. The key to obtaining the desired information is to make the request sufficiently detailed and specific to allow identification of the record(s). Information that would be important to veterinarians would include adverse reaction information for animal drugs, regulatory letters written by the agency, Compliance Policy Guidelines (to direct FDA field staff in enforcement activities) and guidelines implementing regulations. Fortunately most of this information is now available on federal agency Internet home pages. For instance, Warning Letters to manufacturers for violations of Good Manufacturing Practices, and livestock producers or veterinarians involved in causing violative drug

residues may be viewed on FDA's FOIA site. Summary information on reports of adverse drug reactions is available on FDA CVM's home page.

# Regulatory aspects for the drugs and chemicals used in food-producing animals in the European Union

*Arturo Anadón, María Rosa Martínez-Larrañaga and Victor Castellano*

## INTRODUCTION

Drugs and chemicals are essential for the production of animals intended for food. They are used orally or systemically to treat animals or prevent disease and also to promote growth and feed efficiency. The European Union (EU) has already banned antibiotics and growth promoters such as avoparcin, ardacin, zinc bacitracin, virginiamycin, tylosin phosphate, spiramycin, monensin sodium, salinomycin sodium, avilamycin and flavophospholipol added to animal feed due to the fact that the use of these substances could lead to the selection of resistant strains in animals and this form of antibiotic resistance can present problems for antibiotics used in human therapy (Anadón and Martínez-Larrañaga, 1999; Anadón, 2006). Individual animals may be treated (i.e., individual injection or by oral gavage), but it is often more efficient to treat entire groups by mass application by drinking water or feed. Certain mass-medication procedures, called metaphylaxis (a form of prophylaxis), try to treat sick animal outbreaks while medicating others in the group to prevent disease. It is a continuing concern of consumers that various drugs and chemicals could be found at above maximum residue limits (MRLs) in food. The possible effect of such drugs and chemicals on our health and safety depends on the level of exposure to animals, in particular through the foods we eat. Foods containing residues of any of pharmacologically active substances (drugs and biocides) or other undesired

substances (chemicals) above the MRLs could potentially constitute a public health hazard and could create problems in international trade, in particular the substances that have no acceptable daily intake (ADI) and no international MRLs, or their MRLs do not cover species and uses which were considered minor by the sponsors of the data. The establishment of the MRL represents one of the several standard options for risk managers to limit the presence of unwanted substances.

In the EU, the major action was the introduction of requirements for MRLs for residues of veterinary drugs in food of animal origin. Residues are the traces of the drug and its metabolites which remain in the animal and its edible products after treatment with veterinary medicinal products. Depending on the nature of the chemicals and its metabolites they may pose hazards with concurrent risks to consumers when the concentrations are above a safe limit. For instance, certain substances having a thyrostatic, estrogenic, androgenic or gestagenic action, that they leave residues in meat and other foodstuffs of animal origin, may be dangerous to consumers and may also affect the quality of foodstuffs of animal origin. The concern for hormonal residues focuses on chronic exposure to low doses rather than an acute exposure to high doses. In summary, the hazards may be toxicological, pharmacological or microbiological in nature.

The detection of low levels of residues of certain prohibited veterinary drugs in imported animal products by laboratories in the EU at the end of 2001 and during

the first months of 2002 triggered a discussion within the *Codex Alimentarius* Commission whether and how the problems causing such events could be addressed. Several control laboratories in member countries of the EU detected trace amounts of chloramphenicol and nitrofurans in imported animal products (e.g., shrimps, chicken). These findings were triggered mainly by improvements of analytical methods which significantly lowered the levels of detection for residues of these drugs. The question to study is what supranational rules apply if an importing country detects residues of a veterinary drug of which the presence in a food product is not authorized or the use of the drug is not authorized by its own legislation. The relevant international framework which needs to be studied in order to answer this question is provided by treaties and agreements of the World Trade Organization (WTO) and the texts adopted by the *Codex Alimentarius* Commission (CAC) (Lützow, 2004).

The World Trade Organization started to work in 1995, its main objective being the facilitation and promotion of international trade. The main function of WTO is to serve as a monitoring forum for the implementation of a number of treaties which were agreed during the so-called Uruguay round (1986–94) and for settling of trade disputes subject to the rules laid down in those treaties. The more specific principles applied by WTO when developing rules and treaties for trade between her members are: countries may not discriminate trade partners; national and foreign companies shall be treated equally; and trade restrictions are justified for the health protection of humans, animals and plants.

The control of residues of veterinary drugs in animal products intended for human consumption is an issue related to human health which falls as such under the purview of the Agreement of Sanitary and Phytosanitary Measures (SPS). Under the SPS, WTO members can adopt SPS measures that are “necessary for the protection of human and animal health” (Lützow, 2004).

There are a number of veterinary drugs for which Codex has not adopted an MRL. An ADI/MRL may not have been established because the veterinary drug may not have been evaluated, the toxicological data did not support an ADI, the residue data were insufficient, a suitable validated analytical method was not identified or good agricultural practices would result in exceeding the MRL. In the absence of ADI/MRL, national authorities commonly resort to zero tolerance regulatory approaches (where no detectable residue of the veterinary drug in the food is acceptable), with the prevalence of residues of concern potentially changing as analytical method detection capabilities improve.

## VETERINARY MEDICINAL PRODUCTS LEGISLATION

Veterinary medicinal products legislation is regulated in the EU by Directive 2001/82/EC (EC, 2001). In the EU legislative framework for medicines, there are a large number of directives and regulations regarding the issuing of marketing authorizations and the economic regulation of the pharmaceutical market that need to be applied and implemented effectively.

The body of knowledge relating to this implementation is constantly evolving as the EU scientific committees and their working parties develop guidelines and gain experience in new therapies and new technologies.

### Marketing authorization procedures

Marketing authorization applications, which are to be submitted in either a national or Community procedure (i.e., to competent authorities of the Member States and the European Medicines Agency (EMA)), consist of administrative information and the necessary documentation to demonstrate the quality, safety and efficacy of the veterinary medicinal product. This applies to non-immunological and immunological veterinary medicinal products.

A veterinary medicinal product may only be placed on the market in the European Economic Area (EEA) when a marketing authorization has been issued by the competent authority of a member state (or EEA country) for its own territory (national authorization) or when an authorization has been granted in accordance with Regulation (EC) No. 726/2004 (EC, 2004a) for the entire Community (a Community authorization). The marketing authorization holder must be established within the EEA.

The authorization procedures have developed over the years to become very complex with four different routes of application: the centralized or community procedure, the decentralized (DCP), the mutual recognition (MRP) and the national procedure requiring a high level of bureaucracy both for industry and regulators without gain of increased quality, safety and efficacy.

#### Centralized or community procedure

The EMA is the EU body responsible for the scientific evaluation and monitoring of medicines within the “centralized procedure,” a procedure that allows a marketing authorization (license) for a medicine to be obtained in all EU countries simultaneously, on the basis of a single application. For veterinary medicinal products which fall within the mandatory scope of the centralized procedure in accordance with the Annex to Regulation (EC) No. 726/2004

(EC, 2004a), the application is submitted to the EMA. An application shall likewise be submitted to the EMA for veterinary medicinal products which fall within the optional scope of the centralized procedure in accordance with Article 3(2) and 3(3) of Regulation (EC) No. 726/2004 (EC, 2004) where the applicant wishes to obtain a Community marketing authorization. In the “centralized” procedure, the EMA-CVMP is responsible for conducting the initial assessment of veterinary medicines for which an EU-wide marketing authorization is sought. The EMA-CVMP is also responsible for several post-authorization and maintenance activities, including the assessment of any modifications or extensions (“variations”) to an existing marketing authorization.

Following the scientific evaluation and upon receipt of the opinion, the European Commission drafts a Decision on a Community marketing authorization and, after consulting the Standing Committee for Veterinary Medicinal Products, grants a marketing authorization.

#### *Decentralized procedure and mutual recognition procedure*

Evaluation of the operation of marketing authorization procedures has revealed the need to revise the mutual-recognition procedure in order to improve the opportunities for cooperation between Member States. Therefore, Directive 2004/28/EC (EC, 2004b) has introduced the decentralized procedure and the coordination group, which is responsible to settle any disagreements arising from the decentralized and mutual recognition procedures. Both the decentralized and the mutual recognition procedures are based on the recognition by national competent authorities of a first assessment performed by the authorities of one member state. To allow operation of the system, applicants for marketing authorization are obliged to include in their applications copies of any authorization previously obtained in other Member States as well as a list of those Member States in which an application for authorization is under examination (Article 12(3)(n) of Directive 2001/82/EC (EC, 2001)).

In the “mutual-recognition” and “decentralized” procedures, the CVMP arbitrates in cases where there is a disagreement between Member States concerning the marketing authorization of a particular veterinary medicine (“arbitration procedure”). The CVMP also acts in referral cases, initiated when there are concerns relating to the protection of public health or where other Community interests are at stake (“Community referral procedure”).

#### *Decentralized procedure*

The decentralized procedure is the most common route used and takes place in two stages – licensing in

one Member State (“national procedure”) followed by approval in other Member States (“mutual recognition”). In this “national procedure,” regulatory assessors will examine the product’s quality, safety and efficacy and, if content, will advise the competent authority to issue an authorization. Once a marketing authorization has been given in one member state, gaining EU-wide authorization is then possible on the basis of “mutual recognition” whereby the second and subsequent countries’ regulatory authorities should, subject to certain conditions, accept the first country’s “national procedure.” The entire process is known as the decentralized procedure.

For veterinary medicinal products not falling within the mandatory scope of the centralized procedure, the applicant may request one or more concerned member state(s) to approve a draft assessment report, summary of product characteristics, labeling and package leaflet as proposed by the chosen reference member state. An application is submitted to the competent authorities of the reference member state and the concerned member state(s), together with the information and particulars referred to in Articles 12–14 of Directive 2001/82/EC (EC, 2001). The applicant must give an assurance that the dossier, including the proposed summary of product characteristics, labeling and package leaflet, is identical as submitted in all Member States concerned (reference member state and concerned member state). Differences in proposed prescription status and names of the veterinary medicinal product are acceptable, in line with national rules in force.

At the end of the decentralized procedure with a positive agreement, a national marketing authorization will be issued in the reference member state and the concerned member state. The harmonization is maintained through the procedures of Regulation (EC) No. 1084/2003 (EC, 2003) for the examination of variations and the use of the decentralized and mutual recognition procedures for extensions.

#### *Mutual recognition procedure*

This procedure is based on the mutual recognition by concerned member state(s) of a national marketing authorization granted by the reference member state. The concerned member state refers to the reference member state that issued the national marketing authorization on which the mutual recognition procedure is based. At the end of the mutual recognition procedure, a national marketing authorization will be issued in the concerned member state(s). The harmonization is maintained through the procedures of Regulation (EC) No. 1084/2003 (EC, 2003) for the examination of variations and the use of the decentralized and mutual recognition procedures for extensions and renewals.

Independent national procedures

Independent national procedures will continue, but are strictly limited from January 1, 1998 to the initial phase of mutual recognition (granting of the marketing authorization by the reference member state) and to veterinary medicinal products which are not to be authorized in more than one member state.

In addition, as provided for in Article 34(2) of Directive 2001/82/EC (EC, 2001), harmonization of authorizations for veterinary medicinal products authorized in the Community is to be promoted via a coordinated approach for referring veterinary medicinal products, for which divergent decisions have been adopted, to the EMA and the CVMP.

Independent national procedures can also be used for extensions of authorized veterinary medicinal products as far as no *a priori* harmonization has been achieved for the initial marketing authorization.

The safety evaluation for veterinary medicinal product and its residues is based on a package listed in Part 3 of the Commission Directive 2009/9/EC (EC, 2009a) (Table 10.1).

HUMAN HEALTH RISKS FROM DRUG RESIDUES IN FOODS

Edible or target tissues containing veterinary drug residues can pose risk to human health, including direct toxic effects, allergic reactions and increases in bacterial resistance to common antibiotics.

The toxicity of drugs is an inherent part of all uses of medication, and there are differences from one animal or human to another, especially in allergic reactions. Residues of drugs or their metabolites in food products from treated food animals are major considerations in the safety of drugs approved for use in food animals. In Europe, EMA or Member States approve of drug dosages, routes of administration, durations of treatment and withdrawal times, and MRLs are designed to ensure

the safety of foods derived from treated animals. EU regulations have effectively prevented allergenic, toxic and potential carcinogenic drug residues from entering the food supply.

Any adverse reaction is likely to occur due to acute rather than long-term chronic effects.

Acute toxicity effects

For toxicology testing, the sponsor should perform acute and chronic dosing studies. For example, the acute impact of antibiotics is not directly examined in the toxicological studies required in the pre-approval process for veterinary drugs, since the primary concern has focused on chronic effects (i.e., carcinogenesis). The acute studies evaluate animals for problems such as allergies. Acute effects of food-borne drug residues on human health have also been described. These acute effects are defined as those that occur or develop rapidly after single administration of chemical substances. Some examples are hypersensitivity and pharmacological and teratogenic effects.

Hypersensitivity

Meat and other dietary products from treated food animals may contain residues of many antimicrobials or haptenized macromolecules. For small molecules to become immunologic, they must be able to form covalent bonds with macromolecules (i.e., proteins or polysaccharides and polynucleotides). Allergic reactions can be caused by beta-lactam drugs (penicillins and cephalosporins), aminoglycosides, sulfonamides and in a few cases nitrofurans, and tetracyclines. Adverse human reactions are manifested as severe swelling of the skin, serum sickness and shock; less serious reactions such as skin rashes, asthma and fever have been described in sensitive humans due to prior treatment by antibiotics either with the same drug or with one closely related. Drug sensitization can be acquired by antimicrobial

TABLE 10.1 Safety and residue tests in respect of testing of veterinary medicinal products

drugs, their metabolites or degradation products. However, cases of proven allergy to such substances in food are extremely rare, based on clinical and laboratory experience of an immunological reaction, whereas there are less well-substantiated reports blaming antibiotics in up to 50% of cases of chronic urticarial (Dayan, 1993). Reportedly, both epidemiologic and experimental data indicate that levels of penicillin as low as 5 to 10 IU are sufficient to produce an allergic reaction in previously sensitized individuals (Sundlof, 1994). Adverse human reactions occur at very low doses, and it is highly probable that allergic individuals to the drug previously enumerated, when exposed via the food, could suffer an allergic reaction. Probably the reason that few cases are documented is that many cases might be masked with other health conditions, especially in elderly populations, as well as problems with underestimation and underreporting.

Two veterinary drugs may be toxic to humans when used therapeutically. Both are used in veterinary medicine causing adverse reactions by mechanisms involving hypersensitivity and where there is no clear relationship with dose. The first one is chloramphenicol, which may produce two types of bone marrow damage: a reversible dose-related interference with iron metabolism and an irreversible idiosyncratic form of an often fatal aplastic anemia. The mechanism for pathogenesis of aplastic anemia is known, but it may be involved in reduction of the nitro-group to produce toxic metabolites. The reversible form is likely to occur with high doses, a prolonged duration of treatment and in patients with liver disease. Irreversible idiosyncratic aplastic anemia occurs in <1:25,000 patients given chloramphenicol. The onset may be delayed until after therapy has been discontinued. The "gray baby syndrome", which is often fatal, occurs in newborns related to the inability of the immature liver to metabolize chloramphenicol and manifests with standard doses. The second drug is levamisol, which is known to cause reversible agranulocytosis in humans, in which case the mechanism is unknown. The levamisol is widely used as an anthelmintic in animals and the possible occurrence of its residues in animal tissues has caused concern (Woodward, 1991).

### Pharmacological effects

Pharmacological effects may help in the understanding of toxicological phenomena and toxicological effects may result from exaggerated pharmacological responses. These adverse pharmacological effects are generally regarded as acute effects. Similarly, the pharmacological effects of some drugs can be important (e.g., clenbuterol, isoxuprine). This was illustrated by incidents where the  $\beta$ -agonist action of the drug clenbuterol resulted in adverse effects in consumers of liver containing residues of the drug. NOELs can be

determined for pharmacological effects and then used in the calculation of the ADI. It is known that there are two major classes of adrenergic receptors,  $\alpha$  and  $\beta$ , based on the relative effectiveness of several adrenergic compounds to produce a variety of actions in different body tissues. There are two  $\beta$  receptor subtypes,  $\beta_1$  and  $\beta_2$  based on the relative potency of a series of compounds with structural similarities to epinephrine and norepinephrine on physiological processes, including cardiac stimulation and bronchodilation. The  $\beta_2$  receptors predominate in smooth muscles and blood vessels whereas  $\beta_1$  receptors predominate on the heart. Metabolic effects such as glycogenolysis in skeletal muscle or liver and lipolysis are mediated primarily through  $\beta_2$  and  $\beta_3$  receptors are expressed predominantly in adipose tissue.

It is known that the  $\beta$ -agonist clenbuterol has been used illegally as growth promoters in farm animals as a non-steroidal anabolic and metabolism accelerator. Clenbuterol was the first of the synthetic phenethanolamine compounds with demonstrated ability to increase lean and decrease fat in food animals. In addition to their therapeutic effects,  $\beta_2$ -agonists are effective also as "repartitioning agents." As a growth promoter clenbuterol was the first of the synthetic phenethanolamine compounds with demonstrated ability to increase lean and decrease fat in food animals. The use of clenbuterol to enhance lean tissue growth requires a dose that is 10 times higher than the normal therapeutic dose of 0.8  $\mu\text{g}/\text{kg}$  body weight. Factors affecting response to  $\beta$ -adrenergic agonist include level of dietary protein, length of treatment, genotype and sex. Clenbuterol, a selective  $\beta_2$ -agonist, is used as a bronchodilator in human and veterinary medicine and it is available as 0.01 mg and 0.02 mg tablets as well as respiratory solution. In humans, it is used at the recommended oral dosage of 0.02–0.03 mg twice daily. The eye, vitreous humor and retina have been suggested as tissues for residue screening. More recently, accumulation of clenbuterol in hair has been demonstrated and suggested as a sensitive indicator of  $\beta$ -adrenergic agonist residues. In animals in the EU is listed in Table I of the Annex of Commission Regulation (EU) No. 37/2010 (EU, 2010) as allowed substance (Table 10.2).

According to the Directive 2008/97/EC (EC, 2008a) the  $\beta$ -agonists can be used to induce tocolysis (relax the uterus) in cows when calving as well as to treat respiratory problems, navicular disease and laminitis and to induce tocolysis in *equidae*.

In contrast to other  $\beta_2$ -agonists, clenbuterol is well absorbed after ingestion (bioavailability 70–80%). Peak serum levels occur within 3 hours and the elimination half-life was 25–39 hours. At larger doses, it also shows  $\beta_1$ -receptor-mediated (cardiac) effects.

The anabolic effect of clenbuterol, and other long-acting  $\beta_2$ -agonists, appears to be mediated through the  $\beta_2$ -receptors in skeletal muscle. Through its thermogenic

TABLE 10.2 Clenbuterol and its classification regarding maximum residue limits (MRL)

Pharmacologically active substance	Marker residue	Animal species	MRL	Target tissues	Therapeutic classification
Clenbuterol hydrochloride	Clenbuterol	Bovine, <i>Equidae</i>	0.1 µg/kg 0.5 µg/kg 0.5 µg/kg	Muscle Liver Kidney	Agents acting on the nervous system/ Agents acting on the autonomic nervous system
		Bovine	0.05 µg/kg	Milk	

properties, clenbuterol increases energy expenditure and hence reduces muscle glycogen and body fat deposition. In farm animals, clenbuterol accumulates in the lung, liver and kidney, and to a lesser extent in the muscle. Residues of  $\beta$ -agonists in animal tissues used for food may result in serious human health risk.

Clenbuterol has been implicated in several outbreaks of food-borne poisoning follow the consumption of liver, meat and lung of bovine and lung and liver of pig. In 1990, a poisoning incident was reported in Spain where 135 people became ill after consuming beef liver containing clenbuterol residues (Martinez-Navarro, 1990). A second episode of clenbuterol food poisoning was reported one year later in France and affected 22 people, who consumed veal liver, in eight different families in two different sites. The patients suffered tachycardia and tremors for 2 or 3 days. The infective dose is calculated as 1–2 µg/kg/day (Pulse *et al.*, 1991). In 1992, a further episode of clenbuterol poisoning appeared in Spain after ingestion of veal liver. Analysis of liver indicated concentrations of clenbuterol in the range of 160–500 µg/kg. Consumption of 100 g of liver would already exceed the pharmacological effect level of clenbuterol of 5 µg/person. Clenbuterol was detected in 47 urine samples in amounts ranging from 11 to 486 ppm. Other episodes appeared in Hong Kong (1997–98) after the consumption of pig lung (16 people) or pig liver (one people), and in China (2009) 70 people fell ill after eating pork products contaminated with clenbuterol. The common clinical symptoms in food-borne clenbuterol poisoning consisted of muscle tremors, heart palpitation/sinus tachycardia, nervousness, general myalgia, fever, nausea/vomiting, headache, dizziness/vertigo and chills. The latency period varied between 10 minutes and 6 hours, and the duration of symptoms between 90 minutes to 6 days (mostly lasting less than 3 days). Some patients also presented with weakness or confusion. Others developed transient, mild hypokalemia. Electrocardiograms for some patients revealed sinus tachycardia of 120–150 beats/min with ventricular and supraventricular ectopics. Patients with underlying cardiac disease are generally expected to be more susceptible to the cardiac effects of clenbuterol. There were no reported deaths.

One of the side effects of animal treatment with  $\beta$ -adrenergic agonists is increased heart rate. This effect may be either a direct or indirect effect of treatment. The acute toxic effects observed in animals include muscle tremors, tachycardia and nervousness. In addition, treated animals show a higher incidence and severity of hoof lesions. Furthermore, specific histological changes have been observed in treated animals, in particular the formation of vacuoles of epithelial cells in the prostate and Bartholin's gland of male and female calves, respectively. The levels of clenbuterol in the edible tissues are expected to be at the highest.

#### Teratogenic effects

Another acute toxic effect that may occur as a result of exposure to violative animal drug residues is a teratogenic effect. Teratogens are active at very low doses and even brief exposure during a critical period of development can result in a deformation which lasts a lifetime; although the hazard associated with teratogens is severe, the possibility of the event occurring is infrequent. Therefore, the changes to a woman at the critical stage of pregnancy coming in contact with a violative residue are very low (Paige *et al.*, 1997). Other effects caused by a single exposure can be a haemotoxicity, neurotoxicity and endocrine effects.

#### Long-term chronic effects (carcinogenesis)

The long-term chronic toxicity studies identify if problems such as cancer are associated with a specific drug. This study will determine a dose that does not create any health problems. Most residues of veterinary medicines or chemicals occur in food at low concentrations, therefore they rarely pose a chronic or long-term health hazard to consumers. Furthermore those effects as a result of exposure to drug or chemical residues in food are particularly difficult to detect and are certainly under-ascertained as well as under-reported. Carcinogenic studies are a cornerstone of toxicological assessment; however, carcinogenicity studies are rarely used to establish a NOAEL. Special problems emerge where the substance

in a genotoxic carcinogen or a mutagen, due to no threshold, can in theory be identified for it. A substance may not have ADI and MRL for a variety of reasons, in particular when the important pivotal studies were missing or were of insufficient quality and the elaboration procedure had to be discontinued because the sponsor was not prepared to conduct further work. An example can be the carcinogenicity studies. No allocation of an ADI and a no recommendation of MRL mean that safety concerns as a result of the substance were negatively evaluated by a regulatory competent body.

### *Antimicrobial effects*

Antimicrobial drug residues in contaminated foodstuffs can lead to direct toxic effects. The impact may range from sensitizing reactions to drug-inducing organ damage, or may be both. Moreover, to direct toxic effects, many trace amounts of antimicrobial drugs may have the potential to perturb the human gut flora or to disrupt the barrier effect which it exerts, thus permitting the ingress of potentially pathogenic bacteria into the gastrointestinal tract. Antimicrobial residues in food constitute a variety of health hazards to humans which depend on the frequency and degree of residue exposure. The two main risks related to antimicrobials are hypersensitivity reactions, which appear in allergic individuals, and the acquisition by pathogenic microorganisms of resistance to certain antibiotics. These effects may be studied using a variety of experimental models, and they can be taken into account in the calculation of the ADI value.

The standard human food safety assessment for new animal drugs accurately determines the safe concentration for traditional toxicological endpoints as mentioned above. However, the impact of low levels of antibiotics on the intestinal microflora is not directly examined in these toxicological studies. Therapeutic doses of antibiotics can cause adverse effects on the intestinal microfloral ecology (i.e., disruption of the intestinal microflora, or effects on the metabolic activity of intestinal microflora). The adverse effects of antimicrobials are a concern because of the important role that the intestinal microflora plays in maintaining an individual's health. Also perturbation of the intestinal microflora may compromise the effectiveness of other drug therapies and thereby adversely affect public health. Most studies of antimicrobial drugs and their effects on the human intestinal microflora were performed with therapeutic levels of antibiotics. In contrast to the well-documented negative effects of therapeutic dose of antibiotics, the effect of low levels (i.e., ppb or ppm) of antibiotics on perturbing the intestinal microflora is not well defined. It is possible that low doses of antimicrobials agents, such as those found as residues in foods, could alter intestinal enzyme activity and have an effect on certain hormones

and drugs, since in most cases the lowest doses at which the perturbations in the intestinal microflora occur have not been determined. In order to ensure human food safety FDA's CVM considered data gathered from a large number of compounds and determined that the maximum safe concentration for antimicrobial products is 1 ppm in a total diet of 1.5 kg. This equals a maximum antibiotic dose of 1.5 mg/day from consuming residues in food. This level of an antimicrobial residue in food should produce no effects on the intestinal microflora (Paige *et al.*, 1997).

Antimicrobial feed additives have been used in animal production for many decades because of their favorable economic effects in livestock production. Added in low doses to the feed of farm animals, they improved growth and performance and hence were known as antimicrobial growth promoters. Due to the emergence of microbes resistant to antibiotics ("antimicrobial resistance") that are used to treat human and animal infections, the European Commission (EC) decided to phase out, and ultimately ban since January 1, 2006, the marketing and use of antibiotics as growth promoters in animal feed. Since then, the use of antibiotics is now only allowed on veterinary prescription for direct applications or as medicated feed. These restrictions are deemed necessary as antimicrobials may lead to the selection of resistant bacterial strains in animals that could be transferred to humans, by direct contact or via foodstuffs, and subsequently lead to an impairment of the efficacy of antibiotics used in therapy of human infectious diseases.

### *Hormonal effects*

Growth promoting hormones, more particularly steroids and xenobiotics, have been used (legally and illegally) to increase live-weight gain and feed efficiency in various species, more intensively in cattle and to lesser extent in ovine, swine, poultry and fish. Promoting steroid hormones can be divided into four groups of drugs: (1) the natural steroids (oestradiol-17 $\beta$ , progesterone, testosterone); (2) the xenobiotics (trenbolone acetate and zearanol); (3) the synthetic steroids (ethinylestradiol, methyltestosterone, chlormadinone acetate and others); and (4) the diethylstilbestrol and related substances (hexestrol, dienestrol).

The endogenous steroid hormones have a wide range of actions which affect almost all systems of the body. These hormones act by binding with high affinity and high specificity to protein receptors which are located in hormone-responsive tissues. The toxicity or adverse effects of the steroid hormones in humans are apparent even at physiological concentrations. A physiological level of testosterone contributes to acne, baldness, prostatic disease and prostate cancer, cardiovascular disease and peptic ulcers. Physiological concentrations

of estrogens, and to a lesser extent progesterone, have been implicated in premenstrual tension, dysmenorrhea and some cancers of the reproduction system including breast cancer, uterine and cervical cancer (Taylor, 1983). It has been described that the estrogen causes induction of DNA adduct formation. The endogenous hormones are regulated as promoters rather than primary inducers of cancer in hormonally sensitive tissues.

The natural sex steroid hormones estradiol, testosterone and progesterone may be in use illegally for growth promotion.

Diethylstilbestrol (DES) is perhaps the most widely known of the estrogenic growth promoting agents. It is structurally different from the endogenous estrogens in that it does not possess the fused steroid ring structure but does possess two phenolic hydroxyl groups which give DES a special orientation similar to estradiol. The relative binding affinity of DES for the estrogen receptor is 141% (versus 100% for estradiol), but DES is 10–20 times more active than estradiol by the oral route. DES is also metabolized to radical or quinone intermediates which react with cellular macromolecules, including DNA (Metzler, 1984). DES is carcinogenic in humans and in laboratory animals. DES was first used therapeutically in pregnant women in the U.S. to prevent threatened abortion, and in the early 1970s the link was discovered between clear adenocarcinoma in women and their exposure to DES *in utero* (Herbst *et al.*, 1971; Meyers, 1983). Furthermore, it has been shown that DES had other effects on daughters and sons of mothers treated with DES being the most common vaginal adenosis and other gross abnormalities of the reproductive tract (Herbst, 1976).

According to Directive 2008/97/EC the following substances are prohibited: thyrostatic substances; stilbenes, stilbene derivatives, their salts and esters; and estradiol 17 $\beta$  and its ester-like derivatives (see Table 10.3).

The Opinion of the Scientific Committee on Veterinary Measures relating to Public Health (SCVPH) (EC, 2002a) concluded that there is a substantial body of recent evidence suggesting that 17 $\beta$ -estradiol has to be considered as a complete carcinogen, as it exerts both tumor-initiating and tumor-promoting effects, and that the data currently available do not make it possible to give a quantitative estimate of the risk to human health. The mutagenic and genotoxic potential of 17 $\beta$ -estradiol is a consequence of metabolic activation to reactive quinones. The report concludes that 17 $\beta$ -estradiol is not essential in the production of food-producing animals because the use of the available alternatives (especially prostaglandins) by practicing veterinarians is already quite common in the Member States and that the complete prohibition of the use of 17 $\beta$ -estradiol for food-producing animals would have no, or only a negligible, impact on farming and animal welfare (EC, 2002a). Studies on the

TABLE 10.3 Substances not permitted in the EU

1. Substances having a hormonal (stilbenes, stilbene derivatives, their salts and esters, estradiol 17 $\beta$  and its ester-like derivatives) or thyrostatic action, and of  $\beta$ -agonists (with derogations) (Council Directive 96/22/EC) (Directive 2008/97/EC).
2. Pharmacologically active substances listed in Annex, Table 2 of Commission Regulation (EU) No. 37/2010 (Aristolochia spp. and preparations thereof, chloramphenicol, chloroform, chlorpromazine, colchicine, dapsone, dimetridazole, metronidazole, nitrofurans (including furazolidone), ronidazole).
3. Antibiotic growth promoters (avoparcin, ardacin, zinc bacitracin, virginiamycin, tylosin phosphate, spiramycin, monensin sodium, salinomycin sodium, avilamycin and flavophospholipol added to animal feed due to the fact that the use of these substances could lead to the selection of resistant strains in animal and this form of antibiotic resistance can present problems for antibiotics used in human therapy (Council Regulation (EC) No. 2821/98)). Growth factors (quinoxaline-N-dioxides such as carbadox and olaquindox presented a risk to consumers (possess genotoxic and/or carcinogenic properties), to operators or to the animal itself (impairment of adrenal cortex function in pigs) (Commission Regulation (EC) No. 2788/98)).
4. Pharmacologically active substances not listed in the Annex, Table 1 (allowed substances) of Commission Regulation (EU) No. 37/2010 (i.e., MRLs do not cover species and uses which were considered minor by the sponsors of the data).

metabolism of 17 $\beta$ -estradiol in bovine species indicate the formation of lipoidal esters, disposed particularly in body fat. These lipoidal esters show a high oral bioavailability in rodent experiments, thus, the consequence of their consumption needs to be considered in a risk assessment. It is known that experiments with heifers indicated a dose-dependent increase in residue levels of all hormones particularly at the implantation sites. Misplaced implants and repeated implanting, which seem to occur frequently, represent a considerable risk that highly contaminated meat could enter the food chain (EC, 2002a).

Zearanol and trenbolone have been tested for their mutagenic and genotoxic potential in various systems with different endpoints; both compounds exhibited only very weak effects (EC, 2002a).

The new high-technology product bovine somatotropin (BST), used for the enhancement of milk production in cattle, is also not authorized in the EU.

### Carry-over or cross-contamination of the feed of coccidiostats

Different studies have shown that an entire contamination-free production of premixes and compound feeds in existing multi-product plants is not possible in practice (Strauch, 2002, 2003). Practical experience indicates that in feed mills, residual quantities of medicated feedingstuffs may be retained at various points along

the production line and end up at the beginning of the production of another feed product, contaminating subsequent batches of meal as they are processed. This unavoidable carry-over or cross-contamination may occur at all stages of production and processing of feed but also during storage and transport to feed localization (EFSA, 2007) although there are limited data on the amount and frequency of contamination of food with residues of coccidiostats resulting from feeding cross-contamination feedstuffs to food-producing animals (Dorne *et al.*, 2011).

Cross-contamination of feed batches can result in the exposure of non-target animals and induce adverse health effects in these animals due to a specific sensitivity of mammalian species as compared to poultry. Residue formation in edible tissues of non-target species may result in unexpected human exposure through the consumption of animal products (Dorne *et al.*, 2011). Feed additives, such as coccidiostats (polyether and non-polyether ionophores) for poultry, are marketed as premixes, intended to be incorporated into mixed feeds during the mixing and production process. The degree of carry-over depends on the technical facilities and procedures, as well as on product characteristics. For example, the physicochemical characteristics of feed additives can contribute to cross-contamination. The electrostatic properties of some drugs, particularly those in powder form, aggravate the problem, making it more difficult to clean the equipment between batches (Hurd, 1996). The feed additives and premixes also have an important influence on cross-contamination behavior, having the following properties of importance: adhesion strength – adhesion to walls – particle size and density (carrier, substance), and electrostatic properties. The cross-contamination decreases according to the product being less adhesive and electrostatic (EFSA, 2007).

The legal basis of this technological process is based on Regulation (EC) No. 183/2005 (EC, 2005) which replaced Council Directive No. (EC) 95/69 (EC, 95). Article 10 of Regulation No. (EC) 183/2005 (EC, 2006b) provides that feed business operators shall ensure that establishments under their control are approved by the competent authority in case these establishments are manufacturing and/or placing on the market coccidiostats and histomonostats, or premixtures containing coccidiostats and histomonostats.

Carry-over or cross-contamination has been evaluated (Strauch, 2002, 2003; Dorne *et al.*, 2011). Regular investigations have been performed with some coccidiostats, involving lasalocid and nicarbazin (McEvoy *et al.*, 2003; Noser *et al.*, 2006) and showed the persistence of these compounds in various feed batches produced after the intentional incorporation of a polyether ionophore coccidiostat into feed. The health risk to non-target species resulting from the consumption of cross-contaminated feed with coccidiostats at levels of 2, 5 or 10% was evaluated recently

by the European Food Safety Authority (EFSA) and a revision of the risk assessments performed can be found in the paper of Dorne *et al.* (2011). Overall, the toxic syndromes in non-target animal species are related to: (1) incidental consumption of fortified feeds (in most cases intended for chickens) by other animal species; (2) feed-mixing errors or ingestion of premix concentrates with unsafe amounts of ionophores; (3) off-label use, either accidental or intentional, have resulted in adverse reactions in adult poultry (laying hens), ostriches, ornamental and game birds, between others, and humans; and (4) drug interaction with other veterinary medicinal products (target and non-target animal species) (Dorne *et al.*, 2011).

Technical improvement can reduce this cross-contamination considerably and hence limits of cross-contamination can be defined per product to exclude any health risk for human and non-target animal species.

Recently, maximum tolerances for the presence of active substances contained in coccidiostats have been established in food of animal origin and in feeding-stuffs (Commission Regulation (EC) No. 124/2009 (EC, 2009b); Commission Directive 2009/8/EC (EC, 2009b)). The occurrence of unavoidable carry-over or cross-contamination of coccidiostats in non-target feed, even below maximum levels established, may result in the presence of residues of coccidiostats in food products of animal origin (i.e., in feed for which the use of coccidiostats or histomonostats are not authorized, such as feed intended for animal species or categories not provided for in the additive authorization). The maximum levels were set out for the coccidiostats lasalocid sodium, narasin, salinomycin sodium, monensin sodium, semduramicin, maduramicin, robenidine, decoquinate and halofuginone. However, other antimicrobials used as premixes for medicated feedingstuffs have not yet been evaluated for this purpose.

## Reference point for action

With the minimum required performance limits (MRPLs) the European Commission has proposed a temporary measure to address urgent problems related to prohibited or not authorized substances in the EU, in particular in relation to third country trade. Commission Decision 2002/657/EC introduced MRPLs intended to ensure harmonized implementation of Directive 96/23/EC (EC, 1997) for substances for which no permitted limits have been established. Reference point for action of MRPLs are defined as minimum content of an analyte in a sample, which at least has to be detected and confirmed. In contrast to MRLs for substances that may be used in food-producing animals in the EU, the MRPLs would be control tools based on expert advice on feasibility of controls, and other legitimate factors in risk

analysis. Consignments containing residues above the MRPLs would be rejected. If guarantees are provided, they may be returned to the sender.

The MRPLs laid down in Annex II to Commission Decision 2002/657/EC (EC, 2002b) are used as “reference points for action” irrespective of the matrix tested. The Commission Decision 2003/181/EC (EC, 2003) amended Decision 2002/657/EC (EC, 2002b), and established MRPLs for different antimicrobials (see Table 10.4). Where results of analytical tests on products: (1) are at or above the MRPLs, the consignment concerned shall be considered non-compliant with Community legislation and (2) are below the MRPLs, the products will not be prohibited from entering the food chain.

According to Article 1 of Regulation (EC) No. 470/2009 (EC, 2009a), the “reference point for action” is defined as the level of a residue of a pharmacologically active substance established for control reasons in the case of certain substances for which an MRL has not been laid down. The MRPL correspond to the average limit above which the detection of a substance or its residues can be construed as methodologically meaningful. Regulation (EC) No. 470/2009 (EC, 2009c) states that the setting of reference points for action should in no way serve as a pretext for condoning the illegal use of prohibited or non-authorized substances to treat food-producing animals. Therefore, any residues of those substances in food of animal origin should be considered undesirable. Regulation (EC) No. 470/2009 (EC, 2009c) highlighted that the reference points for action shall be reviewed regularly in the light of new scientific data relating to food safety and the outcome of the investigations and analytical tests, and technological progress. In conclusion, the EU would demand from its trading partners prohibition of the use of substances banned in the EU or to establish split systems and ask third countries to provide respective guarantees. In consequence detection of prohibited substances below the MRPL would still be documented and reported.

**TABLE 10.4** Minimum required performance limits (MRPLs) established for several antimicrobials

Substance and/or metabolite	Matrixes	MRPL
Chloramphenicol	Meat, eggs, milk, urine, aquaculture products and honey	0.3 µg/ml
Nitrofurantoines: furazolidone, furaltadone, nitrofurantoin, nitrofurazone	Poultry meat, aquaculture products	1 µg/ml for all

## BIOCIDAL SUBSTANCES USED IN ANIMAL HUSBANDRY

Biocidal substances used in animal husbandry are considered to be biocidal products used for the purposes of caring for and rearing food-producing animals, and to which food-producing animals are exposed during some stage of their lifetime. However, biocidal substances are used in many different situations and residues of biocidal substances may potentially enter the food chain as a result of a number of these uses (including exposure of plants to biocides, exposure of food-producing animals to biocides and contamination of food commodities with biocides). For instance, pesticide is defined as a plant protection product (Regulation (EC) No. 1107/2009) (EC, 2009a) and biocidal products as active substances and preparations containing one or more active substances, put up in the form in which they are supplied to the user, intended to destroy, deter, render harmless, prevent the action of, or otherwise exert a controlling effect on harmful organism by chemical or biological means (Article 1(a) of Directive 98/8/EC (EC, 1998a)). Biocidal product types include those intended to control vertebrates; however, the actual use of such types might give rise to concern. Where a biocidal product identified as an insecticide, acaricide, rodenticide, avicide or molluscicide is authorized according to Directive 98/8/EC (EC, 1998) it is also subject to classification, packaging and labeling according to Council Directive 78/631/EEC (EEC, 1978).

Article 5(1)(b)(iii) of Directive 98/8/EC (EC, 1998a) specifies that for biocidal products/active substances that, as a result of their use, may lead to residues in food, Member States shall ensure that products are only authorized if these residues have no adverse effects on human health.

Article 10 of Regulation (EC) No. 470/2009 (EC, 2009a) provides for the setting of MRLs for pharmacologically active substances used in biocidal products in animal husbandry and specifies that the EMA is responsible for recommending MRLs for these substances.

Under the conditions of use, the biocidal products shall pose only a low risk to humans, animals and the environment. An active substance cannot be included in Annex 1A (list of active substances with requirements agreed at Community level for inclusion in biocidal products) if it is classified as carcinogenic, mutagenic, toxic for reproduction, sensitizing or is bioaccumulative and does not readily degrade. Inclusion of an active substance in Annexes I, IA or IB (list of basic substances with requirements agreed at Community level) shall, where appropriate, be subject to the following: (1) requirements on: (a) the minimum degree of purity of the active substance, (b) the nature and maximum content of certain

impurities, (c) product type in which it may be used, (d) manner and area of use, (e) designation of categories of users (e.g., industrial, professional or non-professional), (f) other particular conditions from the evaluation of the information which has been made available in the context of this Directive; (2) the establishment of the following: (a) acceptable operator exposure level (AOEL), if necessary, (b) where relevant, an acceptable daily intake for humans (ADI) and a maximum residue limit (MRL), (c) fate and behavior in the environment and impact on non-target organisms.

An exhaustive list of 23 product types (PT) can be found in Annex V of Directive 98/8/EC. Main group and product types which can be relevant for substances that may be used in animal husbandry are shown in Table 10.5 and therefore an LMR should be established.

## FEED ADDITIVES LEGISLATION

The new Regulation (EC) No. 1831/2003 (EC, 2003) sets out the rules for the authorization, use, monitoring, labeling and packaging of feed additives. This Regulation replaces Council Directive 70/524/EEC (EEC, 1970).

Directive 70/524/EEC (EEC, 1970) was fully reviewed in 2003 and Regulation (EC) No. 1831/2003 (EC, 2003) represented a major overhaul of the existing EU legislation on feed additives. The Regulation introduced many new aspects into the then existing legislation on feed additives, having been one of the first pieces of food safety legislation adopted following Regulation (EC) No. 178/2002 (EC, 2002b) by introducing the granting of time-limited authorizations valid for a period

of 10 years, the setting up of a Community Reference Laboratory for feed additives, the possibility of establishing MRL for certain additives which may result in residues when added to feed, and the possibility of laying down post-marketing monitoring programs at the time of authorization, as well as other provisions. The Regulation also kept coccidiostats and introduced histomonostats as a new category of feed additive, while establishing the phasing out of the use (and marketing) of the existing antibiotics as feed additives from January 1, 2006, taking into account the risks of selecting bacterial strains resistant to human or veterinary medicine drugs when using antimicrobials as growth promoters.

In 1997, the European Commission introduced the requirement to monitor the occurrence of resistance in animal bacteria associated with the use of antimicrobial feed additives and related substances (EC, 1997), suspending, at the same time, the use of avoparcin as a feed additive in January 1997 and ardacin in January 1998. This obligation was reconfirmed by Council Regulation (EC) No. 2821/98 (EC, 1998a) suspending in December 1998 the use of four other antibiotics (zinc bacitracin, virginiamycin, tylosin phosphate and spiramycin) that had been used as growth promoters in feed under the conditions that their use should be re-examined (Anadón and Martínez-Larrañaga, 1999). Subsequently, the European Commission supported a surveillance program, conducted by industry, to monitor antimicrobial resistance against feed additives in bacteria isolated from pigs and broiler chickens in the slaughterhouses in six European countries. However, as stated in the "White Paper on Food Additives" (adopted January 2000), the European Commission at that time already considered the prohibition or phase-out of antibiotics used as growth promoters within the EU, as part of a broader strategy to control and

TABLE 10.5 Biocides. Main groups and product types to be used in animal husbandry

Main group	Product type	Descriptions
1 Disinfectants and general biocidal products	3	Veterinary hygiene biocidal products: biocidal products used for veterinary hygiene purposes including products used in areas in which animals are housed, kept or transported.
1 Disinfectants and general biocidal products	4	Food and feed area disinfectants: products used for the disinfection of equipment, containers, consumption utensils, surfaces or pipework associated with the production, transport, storage or consumption of food, feed or drink (including drinking water) for humans and animals.
1 Disinfectants and general biocidal products	5	Drinking water disinfectants
3 Pest control	18	Insecticides, acaricides and products to control other arthropods: products used for the control of arthropods (e.g., insects, arachnids and crustaceans).
3 Pest control	19	Repellents and attractants: products used to control harmful organisms (invertebrates such as fleas, vertebrates such as birds), by repelling or attracting, including those that are used for human or veterinary hygiene either directly or indirectly.
4 Other biocidal products	20	Preservatives for food and feedstocks: products used for the preservation of food or feedstocks by the control of harmful organisms.

combat antibiotic resistance. With the aim of avoiding economic losses, in particular in the production of pigs and broiler chickens, and to avoid a significant increase in the use of antimicrobials under veterinary prescriptions, the EC supported the view that the phasing out of antimicrobial feed additives would be easier to pursue if other classes of growth promoting additives could be licensed. Subsequently, several microorganisms or probiotics and an organic acid product were authorized for use as growth promoters. Moreover, enzyme preparations, such as glucanases, xylanases, proteases and phytases, as well as prebiotics (fructo-oligosaccharides and related compounds), were granted marketing authorization.

The individual authorizations contain the characteristics of the products, the identification of the authorization holder, the maximum, minimum and/or recommended dosages, the animal categories in which they can be used, MRL and withdrawal periods where necessary, as well as specific labeling provisions and further conditions where necessary.

The FEEDAP Panel of EFSA carries out its work either in response to requests for scientific advice from risk managers or on its own initiative. Most commonly, and following specific authorization procedures, the European Commission asks EFSA to provide scientific advice and evaluate the safety and/or efficacy of a given substance in the context of its authorization for use in the EU. The scientific assessment performed by the Panel is based on Terms of Reference provided by the European Commission or other European bodies or determined by self-tasking. These guide the Panel approach to each question. Therefore, the authorization of an additive should be granted by the Commission

Article 5 of Regulation (EC) No. 1831/2003 (EC, 2003) states that a feed additive: (1) shall not have an adverse effect on animal health, human health or the environment, (2) shall not be presented in a manner which may mislead the user, and (3) shall not harm the consumer by impairing the distinctive features of animal products or mislead the consumer with regard to the distinctive features of animal product.

According to Regulation (EC) No. 1831/2003 a feed additive is a substance, micro-organisms or preparations, other than feed material and premixtures, which are intentionally added to feed or water in order to perform, in particular, one or more specific functions that are enumerated in Article 5(3) of the Regulation (EC) No. 1831/2003 (EC, 2003): (1) favorably affect the characteristics of feed; (2) favorably affect the characteristics of animal products; (3) favorably affect the color of ornamental fish and birds; (4) satisfy the nutritional needs of animals; (5) favorably affect the environmental consequences of animal production; (6) favorably affect animal production, performance or welfare, particularly by affecting the gastrointestinal flora or digestibility of

feedingstuffs; or (7) have a coccidiostatic or histomonostatic effect; and shall be allocated to one or more of the following categories.

### *Technological additives*

*Technological additives* is defined as any substance added to feed for a technological purpose, and include the following functional groups: (1) preservatives: substances or, when applicable, microorganisms which protect feed against deterioration caused by microorganisms or their metabolites; (2) antioxidants: substances prolonging the storage life of feedingstuffs and feed materials by protecting them against deterioration caused by oxidants; (3) emulsifiers: substances that make it possible to form or maintain a homogeneous mixture of two or more immiscible phases in feedingstuffs; (4) stabilizers: substances which make it possible to maintain the physico-chemical state of feedingstuffs; (5) thickeners: substances which increase the viscosity of feedingstuffs; (6) gelling agents: substances which give a feedingstuff texture through the formation of a gel; (7) binders: substances which increase the tendency of particles of feedingstuffs to adhere; (8) substances for control of radionuclide contamination: substances that suppress absorption of radionuclides or promote their excretion; (9) anticaking agents: substances that reduce the tendency of individual particles of a feedingstuff to adhere; (10) acidity regulators: substances which adjust the pH of feedingstuffs; (11) silage additives: substances, including enzymes or microorganisms, intended to be incorporated into feed to improve the production of silage; and (12) denaturants: substances which, when used for the manufacture of processed feedingstuffs, allow the identification of the origin of specific food or feed materials.

### *Sensory additives*

*Sensory additives* is defined as any substance that improves or changes the organoleptic properties of the feed and/or the visual characteristics of the food derived from animal, and include the following functional groups: (1) colorants: (a) substances that add or restore color in feedingstuffs; (b) substances which, when fed to animals, add colors to food of animal origin; and (c) substances which favorably affect the color of ornamental fish or birds; and (2) flavoring compounds: substances, inclusion of which in feedingstuffs increases feed smell or palatability.

### *Nutritional additives*

The following functional groups are included: (1) vitamins, pro-vitamins and chemically well-defined substances having similar effect; (2) compounds of trace elements; (3) amino acids, their salts and analog; and (4) urea and its derivatives.

### **Zootechnical additives**

*Zootechnical additives* is defined as any additive used to affect favorably the performance of animals in good health or used to affect favorably the environment, and includes the following functional groups: (1) digestibility enhancers: substances which, when fed to animals, increase the digestibility of the diet, through action on target feed materials; (2) gut flora stabilizers: microorganisms or other chemically defined substances, which, when fed to animals, have a positive effect on the gut flora; (3) substances which favorably affect the environment; and (4) other zootechnical additives.

Commission Regulation (EC) No. 429/2008 (EC, 2008b) on implementing rules and guidelines concerning applications for authorization of feed additives for use in animal nutrition in accordance with Regulation (EC) No. 1831/2003 is in application; Regulation (EC) No. 429/2008 (EC, 2008b) provides specific guidelines for the authorization of feed additives. Specific guidelines have been prepared for the FEEDAP Panel of EFSA for additives that are already authorized for use in food, in minor species, as nutritional additives in pets and other non-food producing animals as well as for sensory additives other than flavoring compounds, technological additives (silage additives), technological additives other than silage additives, zootechnical additives (enzymes, microorganisms), zootechnical additives other than enzymes and microorganisms and coccidiostats and histomonostats, among others.

## COMPARATIVE SETTING TOXICOLOGICAL STANDARDS FOR FOOD SAFETY

### **Establishment of European Community maximum residue limits for drugs and feed additives**

The Committee for Medicinal Products for Veterinary Use (CVMP) of the European Medicines Agency (EMA) and Panel on Additives and Products or Substances used in Animal Feed (FEEDAP) of the European Food Safety Authority (EFSA) in order to protect human health, maximum residue limits (MRLs) for veterinary medicinal products (EEC, 1990) and for feed additives (EC, 2003) in foodstuffs of animal origin should be established in accordance with generally recognized principles of safety assessment, taking into account toxicological risks, environmental contamination and well as unintended microbiological and pharmacological effects of residues. Council Regulation 90/2377/EEC (EEC, 1990) regulates

the safety assessment for establishing the MRLs for veterinary medicinal active ingredients. From January 1992, Member States were incapable of granting marketing authorization for veterinary medicines containing new pharmacologically active substances unless an MRL has been established by the EMA-CVMP. Furthermore, the Community had set MRLs for existing pharmacologically active substances in 1997. From January 1, 1997, it was not possible to use any pharmacologically active substance in veterinary medicines intended for food animals for there is no Community MRL.

The safety or risk assessment of residues of veterinary drugs and feed additives is a science-based process involving the four following stages: (1) hazard identification; (2) hazard characterization; (3) exposure assessment ; and (4) risk characterization. Hazard is defined as the potential of a chemical agent to cause harmful effect(s) and risk as a function of the probability that an adverse effect will occur due to the presence of a hazardous compound in food and the severity of the adverse effect (exposure  $\times$  toxicity). It is not possible to completely separate the hazard identification and hazard characterization steps. For hazard identification of veterinary drugs a defined set of animal test covering the entire range of possible adverse effects is routinely required. Information on dose-dependent toxicokinetics properties (rate and extent of absorption, distribution, metabolism and excretion) in test animals, in the target animal species (and in humans when available), is always indispensable for hazard identification and characterization. If metabolites are formed in the target animal species which did not appear in the laboratory animal species, separate testing of those metabolites may be necessary. Other special studies may be required on a case-by-case basis. The standard approach to assessing the safety of chemical contaminants in foodstuffs intended for human consumption is the acceptable daily intake (ADI) defined as an estimate of the amount of a substance in food or drinking water, expressed on a body weight basis, that can be ingested daily over a lifetime without an appreciable health risk (standard human = 60 kg) and it is expressed in units of mg per kg of body weight (FAO/WHO, 2004). For the determination of the no observable adverse effect level (NOAEL), or sometimes a lowest observed adverse effect level (LOAEL), a series of doses is used. In order to establish the dose–effect relationship, the dose levels are chosen in such a way that the highest dose causes an adverse effect and the lowest dose does not produce any adverse effect. The establishment of the ADI from the determination of a NOAEL and application of an appropriate safety factor or uncertainty factor provide the hazard identification and characterization. The ADI approach was developed to take account of effects based on classical toxicology and it is applied to the results of standard toxicity

studies in laboratory animals. The NOAEL for the most sensitive toxicological parameter, normally in the most sensitive species of experimental animal, is used as the starting point (WHO, 1989). In order to arrive at such a NOAEL, a battery of standardized toxicity tests is carried out (i.e., acute toxicity, genotoxicity studies (mutagenicity, clastogenicity), subchronic oral toxicity, chronic oral toxicity/carcinogenicity and specific studies concerning reproduction and developmental toxicity among others) (EC, 2008b). The ADI was calculated by dividing this by a suitable safety or uncertainty factor, conventionally of 100, to account for the differences between test animals and humans (factor of 10) and possible differences in sensitivity between humans (another factor of 10). Depending on the available data set and the nature of substance under study higher or lower safety factors may be applied (e.g., small size of the animal test group, nature of the critical effects, quality of the data). This concept cannot be applicable in cases where certain genotoxic carcinogens do not show a dose-dependent threshold level.

ADIs are related to chemical substances which are deliberately added to a product or ingredient or which can be found on food following, for instance, treatment of crops with pesticide sprays or antifungal agents. A tolerable daily intake (TDI) is an estimate of the quantity of a chemical contaminant to which we may be exposed through environmental contamination, and which when found in food can be ingested daily over a lifetime without posing a significant risk to health.

The ADI represents the total drug residues, parent and all metabolites, that can be safely consumed daily throughout one's life. ADIs also can be developed from pharmacological or microbiological data based on no pharmacological observed effect levels. However, the impact of low levels of antibiotics on the intestinal microflora is not examined directly in these toxicological studies. For substances with microbiological activity what is actually used is the major adverse microbiological effect arising from the effects of residues of antimicrobial drugs in food of animal origin acting on the human gastrointestinal bacteria flora, particularly those acting on the colonic flora. This approach is currently used by

CVMP and JECFA (Joint FAO/WHO Expert Committee on Food Additives) but has never been used by the FEEDAP Panel as can be seen in Commission Regulation (EC) No. 429/2008 (EC, 2008b).

The use of mathematical and statistical approaches for hazard characterization appears to be valuable. One assessment approach that has been used in recent years is the use of statistical estimates based on all the available data in a dose–response series to determine the point of departure from background level response through the use of the benchmark dose (BMD) as a statistical estimate of the NOAEL. The benchmark dose is based on modeling all of the available dose–response data and generally, estimates and excess risk of 10% over background for the response of interest. The benchmark dose lower limit (BMDL) uses the lower bound of a 95% confidence limit on the benchmark dose. The BMD/BMDL approach is just one of a number of approaches that has been developed to refine the ability to characterize the toxicological hazard of a veterinary drug (Edler *et al.*, 2002).

The identification of the residue profile and its decline in the treated animal, resulting in the setting of MRLs, enables the exposure assessment and risk characterization to be determined. Additionally the theoretical maximum daily intake (TMDI) is calculated. The TMDI is an estimate of dietary intake based on multiplying the MRL by the average food consumption for each commodity (i.e., it is assumed that a person with a body weight of 60kg consumes every day over a lifetime 500g of mammalian or poultry “meat” (muscle, liver, kidney, fat) or 300g of fish plus 1500g of milk plus 100g of eggs plus 20g of honey)) and then summing the products (Table 10.6) (EMA-CVMP and WHO, 1989). It is assumed that all the previous tissues and products contain residues at a concentration equivalent to the MRL every day.

Article 14(7) of Regulation (EC) No. 470/2009 (EC, 2009a) states “where it appears necessary for the protection of human health, the classification shall include conditions and restrictions for the use or application of a pharmacologically active substance used in veterinary medicinal products which is subject to a MRL, or for which no MRL has been set” (e.g., not for use in animals

**TABLE 10.7** Conditions and restrictions for the use or application of a pharmacologically active substance used in veterinary medicinal products

Other provisions	Pharmacologically active substances
Not for use in animals from which milk is produced for human consumption (according to Article 14(7) of Regulation (EC) No. 470/2009)	Abamectin (OV); acetylsalicylic acid and acetylsalicylic acid DL-lysine (all food producing species except fin fish); aluminum salicylate (BO); apramycin (BO, OV, PO, CH, RA); bromhexine (BO); carbasalate calcium (all food-producing species except fin fish); clorsulon (BO); closantel (BO); <i>Cimicifugae racemosae rhizome</i> (all food-producing species); cyromazine (OV); decoquinate (BO, OV); derquantel (OV); dicyclanil (OV); difloxacin (BO, OV, CA); doramectin (all mammalian food-producing species); doxycycline (BO); florfenicol (BO, OV, CA); fluazuron (BO); flumethrin (OV); gamithromycin (BO); halofuginone (BO); imidocarb (OV); ivermectin (all mammalian food-producing species); levamisole (BO, OV); mebendazol (OV, CA); methylprednisolone (BO); monepantel (OV, CA); nitroxinil (BO, OV); oxolinic acid (all food-producing species); paromomycin (all food-producing species); phoxim (OV); rafoxanide (BO, OV); <i>Ruta graveolens</i> (all food-producing species); sodium acetylsalicylate and salicylate (all food-producing species except fin fish); tildiposin (BO, CA); toltrazuril sulfone (all mammalian food-producing species); tulathromycin (BO).
For milk MRL further provisions in Council Directive 94/29/EC are to be observed	Alphacypermethrin (BO, OV); cyflutrin (BO, CA); cyhalothrin (BO); cypermethrin (all ruminants); permethrin (BO).
Not for use in animals from which eggs are produced for human consumption (according to Article 14(7) of Regulation (EC) No. 470/2009)	Acetylsalicylic acid and acetylsalicylic acid DL-lysine (POU); amoxicillin (POU); ampicillin (POU); benzylpenicillin (POU); bromhexine (POU); carbasalate calcium (POU); cloxacillin (POU); danofloxacin (POU); dicloxacilin (POU); difloxacin (POU); doxycycline (POU); enrofloxacin (POU); florfenicol (POU); flumequine (POU); kanamycin (POU); levamisole (POU); oxacillin (POU); oxolinic acid (POU); paromomycin (POU); phenoxymethylpenicillin (POU); sarafloxacin (CH); sodium acetylsalicylate (POU); spectinomycin (POU); spiramycin (CH); sulfonamides (POU); thiamphenicol (POU); tilmicosin (POU); toltrazuril (POU); trimethoprim (POU); tylvalosin (POU).
Not for use in fish from which eggs are produced for human consumption (according to Article 14(7) of Regulation (EC) No. 470/2009)	Azagly-nafarelin ( <i>Salmonidae</i> ).
Only for zootechnical use and in accordance with the provisions of Directive 96/22/EC	Altrenogest (PO, <i>Equidae</i> ).
Only for intravaginal therapeutic and zootechnical use and in accordance with the provisions of Directive 96/22/EC	Progesterone (BO, OV, CA, <i>Equidae</i> (female)).
For zootechnical use only	Chlormadinone (synthetic progesterone analog) (BO).
For intravaginal use for zootechnical purposes only	Flugestone acetate (OV, CA); medroxyprogesterone acetate (OV).
For therapeutic and zootechnical purposes only	Norgestomet (bovine); 17 $\beta$ -estradiol (all mammalian food-producing species).

CA = caprine; BO = bovine; CH = chicken; OV = ovine; PO = porcine; POU = poultry; RA = rabbit

from which milk or eggs are produced for human consumption) (see Table 10.7).

Table 10.8, “prohibited substances,” includes substances considered to be unsafe on the grounds of public health (Regulation 37/2010, Table 2 of Annex) (EU, 2010).

### Maximum residue level (MRL)

All new pharmacologically active substances which are intended for use in food animals must have MRLs established prior to licensing. Termed tolerances in the U.S., is defined as the maximum concentration of a residue of a pharmacologically active substance which may be permitted in food of animal origin. In the EU those drugs for which an MRL value should be established

**TABLE 10.8** Prohibited substances in the EU

Substances	Toxicological endpoints
<i>Aristolochia</i> spp. and preparations thereof	nephrotoxicity, mutagenicity and carcinogenicity.
Chloramphenicol	aplastic anemia, carcinogenicity.
Chloroform	mutagenicity and carcinogenicity (lack of data).
Chlorpromazine	behavioral changes.
Colchicine	genotoxicity.
Dapsone	reproductive and teratogenic effects.
Dimetridazole	reproductive and teratogenic effects.
Metronidazole	mutagenicity.
Nitrofurans (including furazolidone)	carcinogenicity.
Ronidazole	mutagenicity.

are governed by Regulation (EC) No. 470/2009 (EC, 2009a), repealing Council Regulation (EEC) No. 2377/90 (EEC, 1990). According to Article 6 of this Regulation the scientific risk assessment (RA) shall consider the metabolism and depletion of pharmacologically active substances in relevant animal species, the type of residues and the amount thereof, that may be ingested by human beings over a lifetime without an appreciable health risk expressed in terms of ADI. Alternative approaches to ADI may also be used. The RA is concerned with the following: (1) the type and amount of residue considered not presenting a safety concern for human health; (2) the risk of toxicological, pharmacological or microbiological effects in human beings; and (3) residues that occur in food of plant origin or that come from the environment. If the metabolism and depletion of the substance cannot be assessed, the scientific risk assessment may take into account monitoring data or exposure data.

The standard approach to assessing the safety of residues in foodstuffs intended for human consumption is based on the determination of the ADI on which, in turn, MRLs are based. The establishment of an ADI from the determination of a NOAEL/LOAEL and application of an appropriate safety factor provide the hazard identification and characterization. The ADI approach takes account of effects based on classical toxicology. There are very potent compounds that exert pharmacological actions through receptor pathways at very low doses; the consequences are very low ADI (or reference dose, RfD) values for human dietary consumption. The  $\beta$ -adrenergic agonists are an example, so the JECFA review of the  $\beta$ -adrenergic agonist ractopamine HCl resulted in a recommendation of an ADI of 0 to 1  $\mu\text{g}/\text{kg}$  body weight/day and MRL of 10  $\mu\text{g}/\text{kg}$  of muscle with higher values in liver and kidney; by contrast this  $\beta$ -adrenergic agonist is not authorized in EU because no ADI or MRL has been set. The ADI can also be determined from microbiological data for substances with microbiological activity. To establish MRLs for a given drug requires provision of the following data: knowledge of dosage schedule (amount, dose interval and duration) and administration route; metabolic and pharmacokinetic data in laboratory animals and each of the target food producing species; distribution and residues depletion data for the major edible tissue (i.e., muscle, fat, liver and kidney) in each target species using radiolabeled drug; validated analytical methods for detection and quantitation of residues, including marker residue; and data defining the effect of residues on food processing. Under EU legislation (Article 14(2) of Regulation (EC) No. 470/2009 (EC, 2009a)) the classification of pharmacologically active substances shall also establish, in relation to each such substance, and, where appropriate, specific foodstuffs or species, one of the following: (1) an MRL; (2) a provisional MRL (pending further data); (3) the absence of the need to establish an MRL; and (4) a prohibition

on the administration of a substance. Those substances included in Annex I, II or III of and amount of residue considered not to present a safety concern for human health. Those substances included in Annex I, II or III of Council Regulation (EEC) No. 90/2377 (EEC, 1990a) are listed in the Annex of Commission Regulation (EC) No. 37/2010 (EU, 2010) (Table 1, allowed substances, where there are listed the pharmacologically active substance, marker residue, animal species, MRL value, target tissues, other provisions (according to Article 14(7) of Regulation (EC) No. 470/2009 (EC, 2009a)) and therapeutic classification, and Table 2 (prohibited substances) (where an MRL cannot be established)) (Table 10.9). This classification substitutes the four annexes of Council Regulation (EEC) No. 2377/90.

#### *Establishment of codex maximum residue limits for drugs and feed additives*

JECFA is an international expert scientific committee that is administered jointly by the Food and Agricultural Organization of the United Nations (FAO) and the World Health Organization (WHO). JECFA serves an independent scientific committee which performs risk assessments and provides advice to FAO, WHO and the member countries of both organizations. The requests for scientific advice are for the main part channeled through the Codex Alimentarius Commission (CAC) in their work to develop international food standards and guidelines under the Joint FAO/WHO Food Standards Programme. The main purposes of this program are protecting health of the consumers and ensuring fair trade practices in the food trade. The advice to CAC on residues of veterinary drugs is provided by the Codex Committee on Residues of Veterinary Drugs in Food (CCRVDF). FAO and WHO

**TABLE 10.9** Active substances are classified under four categories

Regulation (EC) 470/2009	Regulation (EEC) 2377/90
(a) A maximum residue limit.	Annex I. List of pharmacologically active substances for which maximum residue limits have been fixed.
(b) A provisional maximum residue limit.	Annex III. List of pharmacologically active substances used in veterinary medicinal products for which provisional maximum residue limits have been fixed.
(c) The absence of the need to establish a maximum residue limit.	Annex II. List of substances not subject to maximum residue limits.
(d) A prohibition on the administration of a substance.	Annex IV. List of pharmacologically active substances for which no maximum levels can be fixed.

have complementary functions in selecting experts to serve on the Committee. For residues of veterinary drugs, the WHO panel of the Joint Expert Committee is responsible for the toxicological evaluations of the substances under consideration, in order to establish ADIs (or provisional ADIs) when possible. The FAO panel develops specifications for the identity and purity of substances, assessment of residue levels of veterinary drugs in food and quality of the monitoring data; it also proposes limits (MRLs or provisional MRLs) for residues of veterinary drugs in products of animal origin, based on the WHO ADIs and on information about the distribution of the residues in tissues of the target animal. In setting the MRLs, the TMDI is estimated using the exaggerated consumption package for products of animal origin. Veterinary drug residues include parent drugs as well as their metabolites; the metabolites are taken into account if they are toxicologically relevant, i.e., present in a considerable quantity or having a toxicological or pharmacological potential. The MRL is expressed in terms of parent drug levels or in terms of levels of a marker metabolite, if the percentage of the marker metabolite formed from the parent drug is known.

#### *Changes in calculation of MRLs*

In the new JECFA approach, median residue concentration levels are used to derive an estimated daily intake rather than the MRL to better reflect estimates of chronic (lifetime) exposure (WHO, 2006). The MRL and the median concentration are derived from the same time point of the depletion data of the marker residue. The MRL itself is a point on the curve describing the upper one-sided 95% confidence limit over the 95th percentile and the median is the corresponding point on the regression line for the same time point. The JECFA concluded that the TMDI is no longer used as the most suitable estimate of chronic intake. The new procedure uses the same formula as used previously for the calculation of the TMDI, including factors such as the ratio of marker to total residue concentrations; the only exception is the median concentration that replaces the MRL as the point estimate of the residue concentration. Summarizing, the EU throughout the EMA should consider carefully the new MRL JECFA proposals because some impact is expected in the existing MRL assessments.

As indicated in the modification draft of Council Regulation (EEC) No. 2377/90 (EEC, 1990), the European Community contributes in the context of the *Codex Alimentarius* to the development of international standards on MRLs, while ensuring that the high level of human health protection adopted in the European Community is not reduced. The European Community should therefore take over, without a further risk assessment, those Codex maximum residue limits it

has supported in the relevant Codex Alimentarius Commission meeting. Consistency between international standards and Community legislation on residue limits in food will thereby be further enhanced.

With the modification of Council Regulation (EEC) No. 2377/90 (EEC, 1990) a provisional MRL may be established for a pharmacologically active substance in cases where scientific data are incomplete, provided that there are no grounds for supposing that residues of the substance concerned at the level proposed present a hazard for human health

#### *United States of America Food and Drug Administration tolerance setting*

The FDA does not regulate separately the drugs for food-producing animals from the feed additives for animal nutrition. The toxicological assessment of a veterinary drug or a feed additive establishes the basis for identifying the most appropriate *in vitro* and *in vivo* study upon which a no observable effect level (NOEL) and, subsequently, an ADI can be established. Based on the quantity and quality of the data and the scientific interpretation of those data, a safety factor is applied to the NOEL to establish the ADI. The second major component described in that guidance (FDA, 2003a) in regards to safety evaluation is exposure to humans from consumption of residues of toxicological concern in tissues (and milk and eggs, as appropriate). That process begins with metabolism and radiolabeled residue studies in the target animals. The three principal components of this endeavor include comparative metabolism in the toxicological species, total radiolabeled residue and metabolism studies in the food-producing animals, and residue depletion studies to establish the pre-slaughter withdrawal period and, when needed, the milk withdrawal and discard time. Total residue and metabolism study provides information to establish the appropriate marker residue (is the parent drug or any of its metabolites or a combination of any of these with a known relationship to the concentration of the total residue in each of the various edible tissues at the expected withdrawal time) and to determine the target tissue (represent the edible carcass from which residue depletes most slowly and is the edible tissue selected to monitor for the marker residue in the target animal). For FDA, and following the guidance above when the tolerance is based on a toxicological endpoint, the concentration of the marker residue (i.e., the compound used to monitor the depletion of total residue in a food-animal tissue) in the target tissue (i.e., the edible tissue from which the residue depletes most slowly) at the time the total radiolabeled residues in the target tissue have depleted to less than the target tissue in safe concentration, is the target tissue tolerance (word similar to maximum residue limits). When the ADI is based

on a microbiological endpoint (FDA, 2003b), a similar approach is used; however, only residues of microbiological concern are considered. In the FDA approach, when the concentration of the marker residue in the target tissue is less than the target tissue tolerances, total residues in all the edible tissues are less than their respective safe concentrations (i.e., the entire food animal carcass is safe). Safe concentrations of residues in the animal tissues are related to the ADI and food consumption factors. FDA uses the same food consumption factors as are used in the JECFA; however, they are applied differently (Ellis, 2004). FDA assumes that if a person consumes 300 g of muscle tissue, he/she will not consume an allocation of liver or kidney tissue but may consume a full allocation of milk and eggs. The food allocation is 300 g for muscle, 100 g for liver, 50 g for kidney and fat, 1500 g for milk and 100 g for eggs. Therefore, for a safe concentration in muscle for a 60 kg consumer, the ADI (in mg/kg, for example) is multiplied by 60 kg and that value is divided by 0.3 kg. For liver, the denominator will be 0.1 kg and for kidney and fat the denominator will be 0.05 kg. The daily intake of meat products is taken as being one third of the total solid diet of 1500 g (i.e., 500 g). For milk the denominator is 1.5 kg and for eggs it is 0.1 kg.

### Drug withdrawal/withholding periods

A critical factor in the medication of all food-producing animals is the mandatory withdrawal period, defined as the time during which drug must not be administered prior to the slaughter of the animal for consumption. The withdrawal period is an integral part of the regulatory authorities' approval process and is designed to ensure that no significant drug residue is present in the animal at slaughter. Drug residues in food-producing animals should comply with the MRL values for their target tissues in the animal species. The withdrawal period is intended to ensure that no harmful residues remain in edible tissues after slaughter and it is usually established as the slaughter time when residue levels in all the edible tissues are below the MRL. Adherence to the withdrawal period provides assurance that food derived from treated animals will not exceed the MRL (termed tolerances in the USA) for the drug substance. Failure to keep the pre-slaughter withdrawal period while using animal drug is the major cause of violative drug tissue residues in food-poultry production in the EU. Even if the withdrawal period involves only a few days or a few hours, the resulting residues can violate the national regulations against sale of adulterated foodstuffs which can originate distortions of competition between Member States of the EU. Withdrawal period, based on the MRL, is fixed by the regulatory authorities and will take into account the use of veterinary drugs in avian species. For example, for the determination of

the withdrawal period in avian species, six animals per slaughter time are needed. An appropriate withdrawal period is then established to ensure that the residues in edible tissues are depleted below the MRLs. A withdrawal period should be established for the substances with MRLs included in Annex (Table 1) of Regulation (EC) No. 37/2010 (EU, 2010). EMA recommend the harmonization of withdrawal periods using linear regression analysis of log-transformed tissue concentrations determined at the time when the 95% upper one-side tolerance limit was below the MRL with 95% confidence (Anadón *et al.*, 2008a, b, Anadón *et al.*, 2011).

In the EU a veterinary prescription is required for veterinary products for food-producing animals. If it is necessary for a VMP to be prescribed for a species for which it is not licensed or at a dosage higher than the licensed dosage, the veterinarian will specify an appropriate withdrawal period. In exceptional cases, where no medicine is authorized, there is a possibility for the veterinarian to use, for example, products that are authorized in other EU countries or for other animal species. This exception exists to avoid unacceptable suffering of animals. In these cases the veterinarian has to follow specific steps, the so-called "cascade", and has to make sure that there is no risk for the animal(s) concerned and for consumers of food products of animal origin. The exceptional off-label use of authorized medicines is allowed under specific conditions described in Article 11 of Directive 2004/28/EC (EC, 2004b), which are often referred to as the "cascade." EU Member States are obliged to take the necessary measures to ensure that, if there is no authorized VMP in a member state for a specific condition affecting a food-producing species, by way of exception, the responsible veterinarian may, under his/her direct personal responsibility and in particular to avoid causing unacceptable suffering, treat the animals concerned following the algorithm indicated in Table 10.10.

The veterinarian may administer the medicinal product personally or allow another person to do so under the veterinarian's responsibility. For food-producing animals, these provisions apply to animals on a particular holding only; the pharmacologically active substances in the medicinal products used must be listed in the Annex of Regulation No. 37/2010 (Table 1, allowed substances) (EU, 2010), and the veterinarian must specify an appropriate period, which shall be at least 7 days for eggs, 7 days for milk, 28 days for meat from poultry and mammals, including fat and offal, and 500 degree-days for fish meat.

## INDUSTRIAL CHEMICALS

The area of regulations covering industrial chemicals is one of increasing harmonization within the EU. This is

TABLE 10.10 Exceptional off-label use of authorized medicines (“cascade” system)

No authorized veterinary medicinal product (VMD) in a member state for a specific condition	
(a) A VMP authorized in the member state concerned for use for another animal species, or for another condition in the same species; or	
<i>Medicinal product</i>	<i>Medicinal product or imported VMP</i>
(b) A medicinal product for human use authorized in the member state concerned	(b) If there is no such product authorized, either: (i) a medicinal product for human use authorized in the member state concerned, or (ii) a VMP authorized in another member state for use in the same species or in another food-producing species for the condition in question or for another condition may be used;
(c) If, however, there is no such product, a VMP prepared extemporaneously by a person authorized to do so following a veterinary prescription may be used.	

particularly true with regard to the need for providing adequate toxicity data on new chemicals, to allow any potential hazard to humans to be identified, and in the area of labeling of dangerous substances and preparations (i.e., mixtures of substances). A key Directive is Council Directive 67/548/EEC on the approximation of the laws, regulations and administrative provisions relating to the classification, packaging and labeling of dangerous substances, commonly referred to as the Dangerous Substances Directive (EEC, 1967) and its subsequent amendments as well as Council Regulation (EEC) No. 793/93 of March 23, 1993 on the evaluation and control of the risks of existing substances (EEC, 1993). On the other hand, REACH is the Regulation on Registration, Evaluation, Authorization and Restriction of Chemicals (EC, 2006). It entered into force on June 1, 2007. It streamlines and improves the former legislative framework on chemicals of the EU. The main aims of REACH are to ensure a high level of protection of human health and the environment from the risks that can be posed by chemicals, the promotion of alternative test methods, the free circulation of substances on the internal market and enhancing competitiveness and innovation. REACH makes industry responsible for assessing and managing the risks posed by chemicals and providing appropriate safety information to their users. In parallel, the EU can take additional measures on highly dangerous substances, where there is a need for complementing action at EU level. All manufacturers and importers of chemicals must identify and manage risks linked to the substances they manufacture and market. For substances manufactured or imported in quantities of 1 ton or more per year per company, manufacturers and importers need to demonstrate that they have appropriately done so by means of a registration dossier, which must be submitted to the European Chemicals Agency (ECHA). The ECHA may then check that the registration dossier complies with the Regulation and must evaluate testing proposals to ensure that the assessment of the chemical substances will not result in unnecessary testing, especially on animals, but also that adequate information is provided. Where appropriate, authorities may also select

substances for a broader substance evaluation to further investigate substances of concern. Six substances of very high concern will be banned within the next 3 to 5 years unless an authorization has been granted to individual companies for their use. These substances are carcinogenic, toxic for reproduction or persist in the environment and accumulate in living organisms. The following substances are of concern: musk xylene, MDA, HBCDD, DEHP, BBP and DBP.

REACH also foresees an authorization system aiming to ensure that substances of very high concern are properly controlled and progressively replaced by suitable alternative substances or technologies where these are economically and technically viable. Where this is not possible, the use of substances may only be authorized where there is an overall benefit for society of using the substance. In addition, EU authorities may impose restrictions on the manufacture, use or placing on the market of substances causing an unacceptable risk to human health or the environment. The EU Member States authorities are responsible for enforcing REACH through inspections as well as penalties in case of non-compliance. From June 1, 2009, Annex XVII of the REACH Regulation replaced Directive 76/769/EEC (EEC, 1976) on the approximation of the laws, regulations and administrative provisions of the Member States, relating to restrictions on the marketing and use of certain dangerous substances and preparations

## CONCLUSIONS

Complicated and extensive systems for the marketing authorization of veterinary medicinal products and other chemical compounds exist in the EU. These systems attempt to ensure the quality, efficacy (including an objective of overall assessment of the risk/benefit balance of the final product) and safety of veterinary drugs and feed additives. Safety to consumers is of enormous importance and this demands a meticulous assessment of pharmacological, toxicological and residues data.

The marketing authorization procedure for veterinary medicinal products in the EU is of much interest in terms of risk assessment of residues. The main human health risks from drug residues in foods are acute toxic effects and long-term chronic effects. Carry-over or cross-contamination of the feed by coccidiostats can result in the exposure of non-target animal species and induce adverse effects. The pharmacologically active substances contained in biocidal products or in feed additives used in animal husbandry should be submitted to the establishment of MRL as indicated in the current EU regulations. The comparative setting of toxicological standards for food safety are very useful to raise proposal on safety evaluation strategies. Failure to keep the pre-slaughter withdrawal period while using animal drugs is the major cause of violative drug tissue residues in food-poultry production in the EU.

# Safety evaluation of new molecular entities for pharmaceutical development

Rashmi Sharma

## INTRODUCTION

It is well known that the development of a new molecular entity (NME) into a safe and efficacious pharmaceutical product typically may take about one billion dollars in revenues and up to 15 years to launch the product in the market. However, the exceptions are made for entities developed for rare conditions, occurring in small populations (fewer than 200,000 patients) that are classified as orphan drugs and reviewed by the United States Food and Drug Administration (US FDA) under fast-track application. In addition, the drug candidates for indications in life-threatening or serious diseases (e.g., advanced cancer, resistant human immunodeficiency virus (HIV) infection and congenital enzyme deficiency diseases) are also reviewed under fast-track application and the approval process may not require a traditional pharm/tox package during safety reviews.

A number of good books on preclinical development have been published by renowned experts. In addition, there are a large number of regulatory guidelines available to recommend specific studies for pharmacology and toxicology section of the regulatory applications for global submissions and marketing authorization. In the United States, the submission are made to the U.S. Food and Drug Administration (USFDA) and primarily reviewed by either the Center for Drug Evaluation and Research (CDER) or the Center for Biologics Evaluation and Research (CBER). The preclinical safety information is submitted initially in the pharmacology/toxicology section of an investigational new drug (IND) application and later updated with additional chronic and specific toxicology studies in the pharmacology/toxicology

section of the new drug application (NDA), biologics license application (BLA), 510K submission for medical devices or through an abbreviated new drug application (505(b)(2) submission) for a molecular entity that has been previously approved through regulatory process and for which some supporting safety data have been reviewed. The safety data are included and electronically submitted as part of a common technical document (CTD). A CTD contains five modules, in which module 2 consists of non-clinical overview and nonclinical tabulated summaries and module 4 consists of full GLP toxicity reports.

Since 1990, the three regions (U.S., Europe and Japan) have harmonized the requirements for pharmaceutical development; therefore, most of the guidelines follow International Conference on Harmonization (ICH) rules and are considered as ICH guidelines. These ICH guidelines comply with both GLP regulations (21 CFR Part 58, April 2011) as well as with guidelines per Office of Economic Cooperation and Development (OECD, 2004–2006).

The objective of this chapter is to introduce the process of pharmaceutical development and further describe the safety evaluation of NMEs as potential therapeutic agents, in a precise and comprehensible manner. The contents of this chapter may include some information from publicly available regulatory guidelines; however, the complete references have been cited in the reference section and can be consulted for any further detailed information. The chapter does not describe the study designs of GLP toxicity studies since the information is extensive and, therefore, cannot be accommodated in this chapter. The chapter also does not describe all the safety requirements for medical devices.

The development of a pharmaceutical agent is a step-wise process involving an evaluation of both animal and

human efficacy and safety information. Drug development can be broadly classified into (1) preclinical and (2) clinical developments. The first step of preclinical development is known as target discovery, which involves lead identification and where the molecular entity must target a therapeutic mechanism. Once these NMEs are identified, they are validated and optimized for their potency. The discovery process usually involves the use of *in vitro* models. Among hundreds and thousands of molecules, only a handful of potent molecules are able to get through non-clinical and clinical development to establish their safety and efficacy as potential therapeutic agents. The second step of preclinical testing is known as nonclinical testing, in which the lead candidate(s) undergoes thorough safety evaluation in animal models per GLP regulations (21 CFR Part 58, April 2011). Based on the nonclinical data, they are further tested in the clinical trials for their clinical safety, efficacy and marketing authorization.

Typical safety studies are expected to be performed in compliance with Good Laboratory Practice (GLP) regulations for U.S. submissions and per OECD guidelines for European and Japanese submissions. In cases where non-compliance might have occurred, those areas need to be identified and their effect on the outcome of overall safety assessment determined. The lack of full GLP does not necessarily mean that the data from these studies cannot be used to support clinical trials and market authorizations.

## NONCLINICAL SAFETY EVALUATION

A therapeutic agent can be classified as either (1) small molecule, that is chemical in nature and has a molecular weight of less than 10,000Da, (2) biologic agent (larger than 10,000Da, e.g., peptides, protein or DNA derived from recombinant technology or vaccine, oligonucleotides, monoclonal antibodies, etc.) or (3) a medical device either by itself or as a drug-delivery combination.

For small molecules, a standard genotoxicity testing battery is required to determine any potential for possible mutagenicity and carcinogenicity, early in the development. The test battery typically includes two *in vitro* assays (Bacterial Reverse Mutation Assay or Ames test and chromosomal aberration assay or mouse *tk*-lymphoma test) and one *in vivo* mouse micronucleus induction assay. More details of these studies are provided later in the genotoxicity section. The earlier genotoxicity results can be provided for regulatory review in either a pre-IND or IND submission to discuss further plans and make a go/no-go decision. These studies are conducted per GLP regulations as described in genotoxicity guidance ([Guidance for Industry S2B, 1997](#)).

In addition, *in vitro* safety pharmacology studies are also recommended very early in the development ([Guidance for Industry, 57A, 2001 and 57B, 2005](#)). For this purpose, the functional testing of a potassium ion channel, the human ether-a-go-go (HERG) test, is conducted to rule out the possibility of molecular entity, causing the blockage of HERG ion channel which may lead to fatal arrhythmia (torsades de pointes). More details of these tests are provided later in the safety pharmacology section. Exceptions are made for biotechnology-derived products that are not recommended for genotoxicity and *in vitro* safety pharmacology testing.

A nonclinical studies' package includes pharmacokinetic/toxicokinetic studies, acute (single dose), subchronic and chronic (repeat-dose) studies, safety pharmacology, genotoxicity, developmental and reproductive toxicity (DART) studies (based upon requirement), and 2-year carcinogenicity studies. Pharmacology studies can be divided into three categories: primary pharmacodynamics, secondary pharmacodynamics and safety pharmacology.

The objectives of the preclinical safety studies are to define pharmacological and toxicological effects, not only prior to initiation of human studies, but throughout clinical development. The safety evaluation of either a small molecule or a biologic agent generally includes the characterization of toxic effects, with respect to target organs, dose dependence, relationship to exposure and, when appropriate, potential reversibility ([Guidance for Industry M3\(R2\), 2010](#)). Additional specific studies may include phototoxicity studies, immunotoxicity studies, juvenile animal toxicity studies and abuse potential studies, depending upon the intended use.

When conducting safety evaluation, prior safety data from the molecular entities from the same class of compounds with similar structure are always considered to support the safety of the molecular entity of interest. For biotechnology-derived products, appropriate nonclinical safety studies should be determined ([Guidance for Industry ICH S6 \(1997\) and S8 \(2006\)](#)).

Safety evaluation under GLP and OECD guidances requires that the test material should be manufactured per GMP regulations ([Guidance for Industry, CGMP Regulations, September 2006](#)) and must be characterized for its identity, strength, purity, stability over 2 years or longer at room temperature and presence of any impurities. In order to be compliant, it is mandatory to conduct dose concentration analysis (DCA) and stability of test material under conditions of use in any GLP toxicity study. Non-clinical safety testing, in general, should be conducted with consideration to (1) relevant species, (2) age, (3) physiological state, (4) dose, route of administration and clinical treatment regimen, and (5) dose-concentration analysis and stability of the test material under the conditions of use. The relevance of species is especially important for biologic agents that should demonstrate immunogenicity.

## Pharmacokinetic and toxicokinetic studies

Pharmacokinetic/toxicokinetic (PK/TK) analysis is usually conducted in all GLP toxicology studies, including single dose, repeat dose, *in vivo* genotoxicity, reproductive toxicity and carcinogenicity studies ([Guidance for Industry ICH S3A, 1995](#)). The objective of these studies is to determine systemic exposure of a parent compound and/or its metabolites, in relation to dose and time. The main parameters include area under the curve (AUC), maximum concentration ( $C_{\max}$ ) and half-life ( $t_{1/2}$ ) in which time half of the drug is removed from the blood. Blood sampling is usually conducted at short intervals in the first 2 hours and then at larger intervals up to 72 hours. Calculations of these parameters are generally done using Win-Nonlin analysis.

Information on pharmacokinetics (PK) and determination of metabolites through absorption, distribution, metabolism and excretion (ADME) testing (in animal species and *in vitro* systems) are obtained prior to Phase III human clinical trials. Such data are helpful in determining dosing frequency and duration in humans. Nonclinical characterization of a human metabolite(s) is warranted when that metabolite(s) is observed at the exposures greater than 10% of total drug exposure and at significantly greater levels in humans than the maximum exposure seen in the toxicity studies. Such studies should be conducted to support Phase III clinical trials.

For monoclonal antibodies, the immunological properties of the antibody, including its antigenic specificity, complement binding and any unintentional reactivity and/or cytotoxicity towards human tissues distinct from the intended target, should be described. Such cross-reactivity studies should be carried out by appropriate immunohistochemical procedures using a range of human tissues.

## Biological activity/pharmacodynamics (PD)

In general, primary PD studies (*in vivo* and *in vitro*) are intended to investigate the mode of action and/or effects of a substance in relation to its desired therapeutic target. Such studies are generally conducted during the discovery phase of pharmaceutical development and as such are not generally conducted in accordance with Good Laboratory Practices (GLP, 21 CFR Part 58).

Biological activity may be evaluated using *in vitro* assays to determine which effects of the product may be related to the clinical activity.

## Safety pharmacology studies

Safety pharmacology and pharmacodynamics (PD) studies are defined in the [Guidance for Industry ICH S7A](#)

(2001) and [S7B \(2005\)](#). The core battery of safety pharmacology studies includes the assessment of effects on the cardiovascular system, central nervous system and respiratory, renal and gastrointestinal systems, and are recommended to be conducted prior to human exposure. However, when warranted, follow-up safety pharmacology studies can also be conducted during later clinical development. In addition to animal models, *in vitro* and *ex vivo* systems are routinely used that include isolated organs and tissues, cell cultures, cellular fragments, sub-cellular organelles, receptors, ion channels, transporters and enzymes. However, for biotechnology-derived products, *in vivo* studies provide more meaningful data to support their use in humans. The purpose of safety pharmacology studies is to investigate the potential undesirable effects of a substance on physiological functions in the therapeutic range and above. Prior to conducting safety pharmacology studies, some related parameters can be incorporated in the design of general toxicology, PK/TK and clinical studies.

Whether using an *in vitro*, *ex vivo* or *in vivo* model, it is important to define the dose relationship of the adverse effects. In animal models, the dosing route should be as close to the intended clinical route as possible. These studies are performed by single-dose administration and the effects of parent compound and/or its metabolite(s) are evaluated and the results may vary based upon gender.

A list of safety pharmacology tests is described below. Additionally, if the concerns arise for either core battery testing, clinical trials or pharmacovigilance, the follow-up pharmacology studies (listed within parentheses) can be conducted:

1. *Central nervous system.* Motor activity, behavioral changes, coordination, sensory/motor reflex responses and body temperature are evaluated using functional observation battery (FOB; [Mattsson et al., 1996](#)), modified Irwin's test ([Irwin, 1968](#)) or other appropriate tests ([Haggerty, 1991](#)). (Follow-up studies: behavioral pharmacology, learning and memory, ligand-specific binding, neurochemistry, visual auditory and/or electrophysiological examination.)
2. *Cardiovascular system.* Blood pressure, heart rate and electrocardiogram (ECG) are evaluated. (Follow-up studies: cardiac output, ventricular contractility, vascular resistance, the effects of endogenous and/or exogenous substances.)
3. *Respiratory system.* Respiratory rate and other respiratory functions (e.g., tidal volume ([Murphy, 1994](#)) or hemoglobin oxygen saturation) are evaluated. (Follow-up studies: airway resistance, compliance, pulmonary arterial pressure, blood gases and blood pH.)
4. *Renal/urinary system.* Urinary volume, specific gravity, osmolarity, pH, fluid/electrolyte balance, proteins,

cytology and blood chemistry determinations, such as urea nitrogen, creatinine and plasma proteins.

5. *Autonomic nervous system.* Binding of receptors relevant to the autonomic nervous system, functional responses to agonists/antagonists both *in vitro* and *in vivo*, direct stimulation of autonomic nerves and measurement of cardiovascular responses, baroreflex testing and heart rate variability may be used.
6. *Gastrointestinal system.* Gastric secretion, gastrointestinal injury potential, bile secretion, transit time *in vivo*, ileal contraction *in vitro*, gastric pH measurement and pooling.
7. *Other organ systems.* Dependency potential, skeletal muscle, immune and endocrine functions.

Safety pharmacology studies are usually not required for dermal, ocular products or drugs for end-stage cancer patients.

The safety assessment on ventricular repolarization and any proarrhythmic risk is one of the most important aspects of safety evaluation. The QT interval (time from the beginning of the QRS complex to the end of the T-wave) of the electrocardiogram (ECG) is a measure of the duration of ventricular depolarization and repolarization. QT prolongation can either be congenital or induced by pharmaceutical agents. When ventricular depolarization is delayed and the QT interval is prolonged, there is an increased risk of ventricular tachyarrhythmia, including torsades de pointes. The most common mechanism of QT interval prolongation is inhibition of the delayed rectifier potassium channel responsible for  $I_{Kr}$  encoded by human ether-a-go-go (HERG) ion channel protein.

*In vitro* studies for QT prolongation can be conducted using isolated animal or human cardiac myocytes, cultured cardiac cell lines or heterologous expression system for cloned human ion channels and can address proarrhythmic effects. However, animal models allow much more precise testing of ventricular repolarization or associated arrhythmias. Laboratory animal species used for the *in vivo* electrophysiological studies include dog, monkey, swine, rabbit and sometimes guinea pig and ferret. The use of rodents is not recommended, due to the difference in ionic mechanisms of repolarization in adult rats and mice. The dose range should include a dose exceeding the anticipated human exposure but can be adjusted, taking into account any intolerance such as tremors, emesis or hyperactivity.

## General toxicity studies

For safety testing of NMEs, the recommended mammalian species include a rodent and a non-rodent model (e.g., rats and dogs). However, safety evaluation for

biologics usually includes the use of relevant species, in which the test material is pharmacologically active (shows immunogenicity), due to the expression of the receptor or an epitope (in the case of monoclonal antibodies) and demonstrate a similar tissue cross-reactivity profile as for humans. Although two relevant mammalian species are required for safety evaluation programs, in some cases only one relevant species may be sufficient. In the absence of relevant species, the use of transgenic animals expressing the human receptor or the use of homologous protein is considered.

The number of animals used per dose has a direct bearing on the ability to detect toxicity. It is advisable to use at least 10 mice per group or five rats per group, in order to be able to obtain meaningful toxicological data in acute single-dose toxicity studies, especially when the test material is available in small quantities. The suggested number may take into account any possible deaths at high doses, but still reveal statistically meaningful data. Also, a satellite group of animals for any pharmacokinetic/ADME studies would facilitate sufficient sampling for pharmacokinetics as well as clinical chemistry. Both males and females should be used unless the clinical indication is gender specific. The route and frequency of administration should be as close as possible to proposed clinical use. Consideration must be given to the pharmacokinetics and bioavailability of the product in the species being used and to the volume which can safely and humanely be administered to the test animals. In some cases, an alternative to the clinical route may be acceptable provided the modification was done, due to limited bioavailability or limitations due to the route or size/physiology of the animal species.

## Acute toxicity studies

Single-dose studies may generate useful data to describe the relationship of dose to systemic and/or local toxicity. These studies are conducted non-GLP and the highest doses of 2000 mg/kg/day for rodents and 1000 mg/kg/day for non-rodents are usually considered appropriate. The dose selection may also be based upon a 50-fold margin of exposure (usually based on the group mean area under the curve (AUC)) of parent drug or the pharmacologically active molecule of a pro-drug.

Historically, acute toxicity information has been obtained from single-dose toxicity studies in two mammalian species (one rodent and another non-rodent) using both clinical and parenteral routes of administration to define a maximum tolerated dose (MTD) in test species. Acute toxicity results could be useful to support Phase III clinical trials and to predict the consequences of possible human overdose (e.g., depression, pain and dementia). Further details are provided later in the abuse potential section.

### Subchronic and chronic toxicity studies

Dose levels for repeat-dose subchronic and chronic studies are selected based upon MTD values from acute toxicity studies, in order to provide information on a dose–response relationship, including a toxic dose, and to determine a no observed adverse effects level (NOAEL). Generally in repeat-dose toxicity studies, the clinically relevant effects can be adequately characterized, using a range of doses up to MTD or the maximum feasible dose (MFD), achieved by large exposure multiples or saturation. MTD/MFD levels are especially important for repeat-dose developmental and reproductive toxicity (DART) and carcinogenicity study designs to select less toxic doses.

NOAEL is used to calculate first safe human equivalent dose (HED) for Phase I clinical trials in healthy volunteers and details are provided in the estimation of first dose in human section.

The route and dosing regimen (e.g., daily versus intermittent dosing) is similar to the intended clinical use and often includes PK/TK analyses. The inclusion of a recovery period (especially in biopharmaceuticals) in study designs is important to determine the reversal or potential worsening effects, and/or any delayed toxic effects.

Usually 28-day repeat-dose toxicity studies in two species (one rodent and another non-rodent) may support any clinical trial up to 2 weeks. For therapeutic agents in chronic indication, 6 months' rodent and 9 months' non-rodent studies generally support dosing for longer than 6 months in clinical trials. This duration of animal dosing has generally been 1–3 months for most biotechnology-derived pharmaceuticals. For biopharmaceuticals intended for short-term use (e.g., less than or up to 7 days) and for acute life-threatening diseases, repeat-dose studies up to 2 weeks' duration have been considered adequate to support clinical studies as well as marketing authorization. The recommended duration of repeat dose toxicity studies to support the conduct of clinical trials is described in Table 11.1. The durations of repeat-dose toxicity studies to support marketing is described in Table 11.2.

### Local tolerance studies

It is preferable to evaluate local tolerance, by the intended therapeutic route, as part of general toxicity studies. In cases where the anticipated systemic exposure (area under the curve (AUC) and maximum plasma concentration ( $C_{max}$ )) is covered by the existing toxicology package, the endpoints in the local tolerance study can be confined to clinical signs and macroscopic and microscopic examination of the application site.

TABLE 11.1 Recommended duration of repeat-dose toxicity studies to support the conduct of clinical trials

Maximum duration of clinical trials	Recommended minimum duration (rodents)	Recommended minimum duration (non-rodents)
Up to 2 weeks	2 weeks <sup>a</sup>	2 weeks <sup>a</sup>
Between 2 weeks and 6 months	Same as clinical trial <sup>b</sup>	Same as clinical trial <sup>b</sup>
>6 months	6 months <sup>b,c</sup>	9 months <sup>b,c,d</sup>

<sup>a</sup>In the U.S., alternate extended single-dose toxicity studies can support single-dose human clinical trials.

<sup>b</sup>Clinical trials of longer than 3 months can be initiated if 3-month rodent and non-rodent studies are available.

<sup>c</sup>In case pediatric population is the intended population, long-term testing in juvenile animals can be conducted.

<sup>d</sup>In the EU, 6-month non-rodent studies are acceptable but no need to conduct additional 6-month study for longer duration. In the U.S. and Japan, 6-month non-rodent studies are acceptable if immunogenicity occurs, for treatment of migraine, erectile dysfunction and herpes simplex, or for drugs for life-threatening conditions such as cancer.

TABLE 11.2 Recommended duration of repeated-dose toxicity studies to support marketing

Duration of indicated treatment	Rodent	Non-rodent
Up to 2 weeks	1 month	1 month
>2 weeks to 1 month	3 months	3 months
>1 month to 3 months	6 months	6 months
>3 months	6 months	9 months <sup>c,d</sup>

N.B. Refer to notes c and d in Table 11.1.

For parenteral products, the evaluation for local tolerance at injection sites is conducted before large Phase III clinical trials. Local tolerance studies are generally not recommended in the United States. Japan and the European Union (EU) recommend single-dose paravenous administration for the intravenous route.

### Genotoxicity studies

Genotoxicity tests conducted *in vitro* and *in vivo* are designed to test any genetic damage caused directly or indirectly. Any damage to DNA in the form of gene mutations, large -scale chromosomal damage, recombinant and numerical chromosome changes is considered essential for heritable effects and in the multistep process of malignancy. Compounds that cause such changes have a potential to cause cancer in humans.

For registration of pharmaceuticals, a standard three-test genotoxicity battery is used (Guidance for Industry ICH S2B, 1997) that consists of (1) bacterial reverse mutation assay or Ames test conduct using *Salmonella* strains, (2) *in vitro* chromosomal aberrations (structural and

numerical) test conducted either using bone marrow or peripheral blood from animals or humans (alternatively, mouse *tk*-lymphoma assay may also be conducted to detect gene mutation and clastogenic effects) and (3) *in vivo* micronucleus induction test in mice that may also include additional ADME analysis to determine if a metabolite may cause such induction of micronuclei.

The negative results in this test battery usually provide a sufficient level of the absence of genotoxic potential. However, compounds giving positive results in this standard battery may have to be evaluated more thoroughly. Even if a compound is tested negative in this battery but shows any evidence of tumor response, it needs more extensive testing.

Completion of genotoxicity battery is required before the initiation of Phase II trials. The type of genotoxicity studies routinely conducted for small molecules are not applicable to biotechnology-derived pharmaceuticals.

## Carcinogenicity studies

Conditions relevant for carcinogenicity testing are discussed in the [Guidance for Industry ICH S1C\(R2\) \(2008\)](#) document and conducted to support marketing application. Typically, when bacterial reverse mutation assay and an *in vivo* genotoxicity assay are tested positive, the carcinogenicity studies may be required as a Phase IV commitment and be conducted for post-marketing approval. However, a lengthy clinical study duration for chronic indication alone is not considered to be a significant reason for these studies. For pharmaceuticals developed to treat certain serious diseases for adults or pediatric patients, carcinogenicity testing, if recommended, can also be concluded for post-marketing approval. Recently, the medical devices intended for long-term use have also been requested to be tested in carcinogenicity studies.

For biologics, standard carcinogenicity bioassays are generally considered inappropriate. However, the products (e.g., growth factors, immunosuppressive agents, etc.) that may have the potential to support or induce proliferation of transformed cells and clonal expansion, possibly leading to neoplasia, should be evaluated in a rodent model. Standard 2-year carcinogenicity testing is required using mice and rats including both males and females. Alternatively, suitable transgenic rodent models can also be used in a much shorter (~9 month) study.

Irrespective of the nature of the molecular entity, careful consideration should be given to the rationale and selection of doses ([Guidance for Industry Carcinogenicity Study Protocol Submissions, 2002](#)). Prior to the design and conduct of a standard 2-species/2-year carcinogenicity testing, it is recommended to

follow the ICH guidances ([ICH S1C\(R\), 2008](#)) and for a proposed testing plan to be reviewed by the Carcinogenic Assessment Committee (CAC). For this purpose, a 90-day repeat-dose toxicity study using the same dosing route, diet and rodent strain as intended for carcinogenicity study is required. Additionally, supporting PK/TK data including the exposure (AUC) at the maximum recommended human dose (MRHD) from clinical trials, plasma protein binding and genotoxicity data are helpful.

## Developmental and reproductive toxicity (DART) studies

Guidelines for reproductive toxicity were developed by the Expert Working Group (Safety) of the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use ([Guidance for Industry ICH S5A, 1994](#)). For reproductive testing, the animals are treated during defined stages of reproduction that reflect human exposure. In order to allow detection of exposure, observations should be continued through one complete life cycle, i.e., from conception in one generation through conception in the following generation. Testing can be subdivided into the following six stages:

- 1 Premating to conception (adult male and female reproductive functions, development and maturation of gametes, mating, behavior and fertilization).
- 2 Conception to implantation (adult female reproductive functions, preimplantation development, implantation).
- 3 Implantation to closure of the hard palate (adult female reproductive functions, embryonic development, major organ formation).
- 4 Closure of the hard palate to the end of pregnancy (adult female reproductive functions, fetal development and growth, organ development and growth).
- 5 Birth to weaning (adult female reproductive functions, neonate adaptation to extrauterine life, preweaning development and growth).
- 6 Weaning to sexual maturity (post-weaning development and growth adaptation to independent life, attainment of full sexual function).

The animals should be of comparable age, weight and parity at the start being young, mature adults at the time of mating with females being virgin. Usually, rats are predominantly used because of their practicality and the large amount of background knowledge. However, in embryotoxicity studies, a second mammalian species traditionally has been required and rabbit is the preferred choice as a "non-rodent" due to extensive background

knowledge, availability and practicality. Alternatively, non-human primates may also be used for the purpose.

Selection of dosages in design of the reproductive toxicity study should be based on pharmacology, acute and, if available, chronic toxicity and PK/TK studies. A repeat-dose toxicity study of about 2 to 4 weeks' duration provides a close approximation to the duration of treatment in segmental designs (Segments I (embryofetal), II (prenatal) and III (postnatal)). An evaluation of male reproductivity is advised in the repeated-dose toxicity studies. It is important to characterize and minimize the risk of unintentional exposure of the embryo or fetus when including WOCBP (women of child-bearing potential) in clinical trials. DART studies are usually required to be completed before the Phase III clinical trials begin. In all the three ICH regions, the pre- and postnatal development studies should be submitted for marketing approval.

In addition to therapies indicated for women of child bearing potential (WOCBP), DART studies are also recommended for the development of investigational and therapeutic vaccines for infectious diseases ([Guidance for Industry FDA, vaccine guidance, 2006](#)). Since, the indication of these vaccines is for immunization in adolescent and adults, there is increasing concern about the unintentional exposure of an embryo/fetus. Therefore, the recommendations pertaining to such studies are specially indicated in WOCBP and pregnant women. Since the pregnant women are usually excluded from the clinical trials, data from developmental toxicity studies in animal models may frequently present the only information regarding developmental risk to be included in the product labeling.

Vaccines are a heterogeneous class of preventive or therapeutic products that may cause an immune response(s) and prevent and/or lessen the severity of one or more infectious diseases. A vaccine may be a live attenuated preparation of bacteria, viruses or parasites, inactivated (killed) whole organisms, living irradiated cells, crude fractions or purified immunogens, including those derived from recombinant deoxyribonucleic acid (DNA) in a host cell, conjugates formed by covalent linkage of components, synthetic antigens, polynucleotides (such as plasmid DNA vaccines), living vectored cells expressing specific heterologous immunogens or cells pulsed with immunogens. Antigens may be presented plain or derived in combination with other antigens, adjuvants, additives and other excipients.

Clinical experience from pregnant women may be helpful in the evaluation of the potential for any adverse outcome on the viability and development of the offspring, help design and monitoring of appropriate non-clinical studies and for product labeling. In addition to an immune response in pregnant females, it is necessary to verify exposure of the fetus to the maternal

antibodies. Males may be included in Phase I, II and III clinical trials in the absence of non-clinical male fertility studies.

## Pediatric drugs studies

For safety evaluation of therapeutics intended for the treatment of pediatric patients, non-clinical toxicity studies are conducted using juvenile animals that can provide meaningful prediction of toxicity in pediatric patients. Such testing is limited to safety effects that cannot be adequately, ethically and safely assessed in pediatric clinical trials. The effects that pose most concern are the irreversible serious adverse effects ([Guidance for Industry, Pediatric drug products, 2006](#); [Guidance for Industry FDA, pediatric, 2006](#)). A survey conducted by the American Academy of Pediatrics showed that the majority of the drugs listed in the Physician's Desk Reference lack information on safety and/or efficacy for pediatric use (Committee on Drugs, Pediatrics, 1995). However, recent pediatric legislation, including the [Best Pharmaceuticals for Children Act \(BPCA, 2007\)](#) and the [Pediatric Research Equity Act \(PREA, 2003\)](#), have been helpful in obtaining the critical pediatric safety and efficacy information in drug product labels. Safety data from adult animals and humans are helpful in supporting juvenile animal and pediatric studies. Since developmental processes in pediatric patients may differentially affect drug pharmacokinetics and pharmacodynamics compared to adult therapeutic use, juvenile animal studies may assist in identifying postnatal developmental toxicities that are not adequately assessed in reproductive toxicity assessments.

The delicate and immature organ systems (brain, kidneys, lungs, immune system, reproductive system and gastrointestinal system) of pediatric patients, in terms of developmental changes in metabolism (including the maturation rate of Phase I and II detoxification enzyme activities), body composition (i.e., water and lipid partitions), receptor expression and function, growth rate and organ functional capacity, make them more susceptible to modifications or disruption by drugs than the adults. Some of the examples of such drugs include acetaminophen, valproic acid, chloramphenicol, inhaled corticosteroids, aspirin and lamotrigine.

Juvenile animal testing may be useful in assessing potential developmental age-specific toxicities. The toxicological assessments are done on active and inactive ingredients in addition to any excipients. Any concern for postnatal development can be addressed either in juvenile animal studies or by modified study design (e.g., modification of segment III reproductive toxicity studies to include animals of similar developmental status as the pediatric population of concern).

The pharmacokinetic analysis of clinical studies in pediatric subjects does not involve long-term exposure because they are generally less than 6 months long. However, if the drug is indicated for chronic use, some assessment of the long-term development effects in animals should be made before marketing and the initiation of long-term clinical studies. When there have been reports of adverse effects with off-label use in pediatric patients and there are inadequate data to evaluate the relationship between the drug and the adverse effects, completed juvenile animal studies are needed before initiation of pediatric clinical studies. For serious life-threatening pediatric conditions, safety studies are considered on a case-by-case basis.

Consideration should be given to the age of the intended population and the corresponding stage of postnatal development. Most drugs that are intended for pediatric use (12 years and older) have established efficacy and safety profiles in adult humans. The embryofetal development is especially sensitive to perturbation during organogenesis, in which tissues that undergo significant postnatal development are studied in juvenile animals for those specific effects, even when the primary postnatal development is studied in juvenile animals for those specific effects.

Among preferred testing species, rats and dogs have been the rodent and non-rodent species of choice. In some circumstances, minipigs, pigs and monkeys can also be used. The choice of species depends on the pharmacology, pharmacokinetics and toxicology of the therapeutic agent, comparative developmental status of the major organs of concern between juvenile animals and pediatric patients and sensitivity of the selected species to a particular toxicity. Typically, one animal species may be sufficient to evaluate toxicity endpoints for therapeutics that are well characterized in both adult humans and animals using modified perinatal and postnatal developmental studies.

Studies include the measurement of overall growth (e.g., body weight, growth velocity per unit time, tibial length), clinical observations, measurement of organ weights, gross and microscopic examinations, clinical pathology, assessment of sexual maturation (mating, fertility) and neurobehavioral testing, particularly in rodents. For developmental neurotoxicity assessments, well-established methods should be used to monitor key central nervous system (CNS) functions, including assessments of reflex ontogeny, sensorimotor function, locomotor activity, reactivity, learning and memory.

Generally, biomarkers of adverse effects could be identified in non-clinical studies that should be useful in monitoring the human subjects in clinical trials. Prior to the initiation of trials in pediatric populations, results from repeat-dose toxicity studies of appropriate duration in adult animals, the core safety pharmacology package and the standard battery of genotoxicity tests should be

available. If a study is warranted, one relevant species, preferably rodent, is generally considered adequate.

The appropriateness of carcinogenicity testing should be addressed before long-term exposure in pediatric clinical trials. However, unless there is a cause for concern (e.g., evidence of genotoxicity in multiple tests, or concerns for procarcinogenic risk based on mechanistic considerations), carcinogenicity studies are not recommended to support the conduct of pediatric clinical trials.

## Immunotoxicity studies

Immunotoxicity studies are generally conducted for biologics and biotechnology-derived products (also classified as large molecules). Biotechnology-derived pharmaceuticals were initially developed in the early 1980s. Among biologics are the products derived from the characterized cells through the use of a variety of expression systems that include bacteria, yeast, insect, plant and mammalian cells. The intended use may include *in vivo* diagnostic, therapeutic or prophylactic uses. The active substances include proteins and peptides, their derivatives and products of which they are components; they could be derived from cell cultures or produced using recombinant plasma factors, fusion proteins, enzymes, receptors, hormones and monoclonal antibodies. Other products include recombinant DNA protein vaccines, chemically synthesized peptides, plasma-derived products, endogenous proteins extracted from human tissue and oligonucleotide drugs.

Regulatory standards for biotechnology-derived pharmaceuticals have been generally comparable among the three ICH regions namely European Union, Japan and United States and all three regions have adopted a flexible case-by-case, science-based approach to preclinical safety evaluation needed to support clinical development and marketing authorization. Per ICH guidances (S6, 1997 and S8, 2006), all new human pharmaceuticals should be evaluated for the potential to produce immunotoxicity using standard toxicity studies, and additional immunotoxicity studies conducted as appropriate based on a weight-of-evidence review, including immune-related signals, should be completed before exposure of a large population of patients (e.g., Phase III). Immunogenicity may be related to either suppression or enhancement of immune response. Suppression can lead to decreased host resistance to infectious agents or tumor cells whereas the enhancement can exaggerate autoimmune diseases or hypersensitivity.

Immunosuppression or enhancement can be associated with two distinct groups: (1) drugs intended to modulate immune function for therapeutic purposes (e.g., to prevent organ transplant rejection) and (2) drugs not intended to affect immune function but cause

immunotoxicity due to necrosis or apoptosis of immune cells or interaction with cellular receptors (antiproliferative agents such as cancer drugs). Additional testing may be based on (1) findings from standard toxicity studies, (2) the pharmacological properties of the drug, (3) the intended patient population, (4) structural similarities to known immunomodulators, (5) the disposition of the drug and (6) clinical information.

Standard toxicity studies include (1) hematological changes such as leukocytopenia/leukocytosis, granulocytopenia/granulocytosis or lymphoma/lymphocytosis, (2) alterations in immune system organ weights and/or histology (e.g., changes in thymus, spleen, lymph nodes and/or bone marrow), (3) changes in serum globulin that occur without a plausible explanation, such as effects on the liver or kidney, which can be an indication that there are changes in serum immunoglobulins in the liver or kidney, and can be an indication that there are changes in serum immunoglobulins, (4) increased incidence of infections, and (5) increased occurrence of tumors can be viewed as a sign of immunosuppression in the absence of other plausible causes such as genotoxicity, hormonal effects or liver enzyme induction. Similar to the assessment of risk with toxicities in other organ systems, the assessment of immunotoxicity should include (1) statistical and biological significance of the changes, (2) severity of the effects, (3) dose-exposure relationship, (4) safety factor above the expected clinical dose, (5) treatment duration, (6) number of species and endpoints affected, (7) changes occurring due to stress, (8) possible cellular targets and/or mechanism of action, and (9) reversibility of effect(s). Additionally, T-cell-dependent antibody response (TDAR) and immunophenotyping of leukocyte populations can be conducted to identify the specific cell population.

For immunotoxicity studies, the choice of an animal species depends on the ability to develop an immune response to the vaccine antigen. Most human vaccines are immunogenic to rodents or rabbits. In some cases, only non-human primates may show an adequate immune response.

The measurement of antibodies associated with administration of these types of products is performed in repeat-dose toxicity studies and immune response (e.g., titer, number of responding animals, neutralizing or non-neutralizing) is correlated with any pharmacological and/or toxicological changes.

Some information on absorption, disposition and clearance in relevant animal models should be available prior to clinical studies that may provide margins of safety based upon exposure. Since the expected consequence of metabolism of biotechnology-derived pharmaceuticals is the degradation to small peptides and individual amino acids the classical biotransformation studies as performed for pharmaceuticals are not needed.

A generally accepted study design in rodents is a 28-day study with consecutive daily dosing but seldom using non-rodent species. Usually, both genders are used in these studies, excluding non-human primates, unless the intended use is in only one gender of the human population. Multiple dose levels are used with high doses above NOAEL dose, in order to determine dose-response relationships and the dose at which no immunotoxicity is observed.

DART studies are generally required for vaccines in order to determine the adverse effects on pregnant/lactating female animals and development and growth of the embryo/fetus and the offspring. In such studies, the females must be exposed to the vaccine during the interval from implantation through closure of the hard palate and also at later stages of pregnancy. The offspring should be followed to weaning and observed for growth and development. In addition, the immunological assessment may include the measurement of vaccine-induced antibody response to verify exposure to the embryo/fetus to maternal antibody.

### Phototoxicity studies

An evaluation of the non-clinical drug distribution to skin and eye should be completed to inform any human risk. An experimental evaluation (non-clinical *in vitro/in vivo* or clinical) of phototoxic potential should be undertaken before exposure of large numbers of subjects (Phase III). Alternatively, a direct assessment of phototoxic potential in a non-clinical or clinical study can be undertaken. If the phototoxicity assessment indicated a potential photocarcinogenic risk, the risk can usually be adequately managed in patients by protective measures including a warning statement in the informed consent for clinical trials and in product information for marketing.

### Abuse liability testing

Abuse potential refers to a drug that is used in non-medical situations, repeatedly or even sporadically, for the positive psychoactive effects ([Guidance for Industry FDA Abuse Potential, 2010](#)). The guidance for abuse potential of drugs is intended to assist with products that mainly affect the central nervous system and such drugs are regulated under the Controlled Substances Act (CSA; 21 U.S.C. 811, 2007). In addition, the drugs that are structurally and pharmacologically similar to other drugs with known potential of abuse such as antipsychotic drugs that may cause sedation, euphoria or mood changes are also regulated in the same way. The CSA has four schedules to categorize the substances, depending upon the schedules.

The purpose of scheduling substances under the CSA is to minimize abuse and diversion while affording appropriate therapeutic areas. The controls may include manufacturing and production quotas, varying degrees of manufacturing and distribution site requirements and import/export regulations. Prescribers, dispensers, drug manufacturers and distributors are required to register with the Drug Enforcement Administration (DEA).

Non-clinical data collected early in the drug development process can be useful in identification of early indicators of abuse potential that would typically be available before first human dose and include the PK/PD profile to identify the duration of action, similarity of chemical structure to known drugs of abuse, receptor binding profile and behavioral/clinical signs from *in vivo* non-clinical studies.

Three types of studies are often completed to evaluate the potential for abuse liability: (1) drug discrimination, (2) self-administration of the compound and (3) an assessment of withdrawal. When conducted, studies of drug discrimination and self-administration are generally stand-alone.

Among the types of animal abuse potential studies, self-administration tests assess the rewarding properties of a drug. Also, in the drug discrimination method, the animals indicate whether a test drug produces physical or psychotic perceptions similar to those produced by a known drug of abuse. In addition, the psychomotor tests assess the effects of the test drug on motor functioning in comparison with the effects of well-characterized drugs of abuse.

Pertinent data can be obtained during Phase III clinical trials that can provide support not only for therapeutic potential but also for abuse, dependence on potential drug diversion and accountability. Sometimes, abuse-relevant adverse event data for non-patient healthy populations can be obtained from single- and multiple-dose pharmacokinetic studies and electrocardiographic studies.

Any U.S. or foreign post-market experience and epidemiological data regarding misuse and abuse of a drug may be useful in decisions about scheduling a substance under the CSA and labeling a drug under the Food, Drug and Cosmetic Act (FDCA) of 1938. Labeling and drug scheduling play different roles in encouraging safe and appropriate use of drugs with abuse potential, as well as in minimizing the actual abuse, and the diversion. Information on abuse potential is generally conveyed to the health care professionals and patients through appropriate labeling which is the cornerstone of risk minimization for most of the approved drugs.

## Impurities qualification

The approaches for qualifying impurities and degradants are outlined in ICH guidances ([Guidance for Industry](#)

[Q3A \(R\), 2008](#) and [Q3B \(R2\), 2006](#)). An impurity can occur in a new drug either as a result of chemical synthesis or the byproduct of degradation process. Impurities can be classified into (1) organic impurities (process and drug related), (2) inorganic impurities and (3) residual solvents. Organic impurities can arise during the manufacturing process and/or storage of the new drug substance. Inorganic impurities can result from the manufacturing process. They are normally known and identified and may include: (1) reagents, ligands and catalysts, (2) heavy metals or other residual metals, (3) inorganic salts and (4) other materials (e.g., filter aids, charcoal).

Solvents are inorganic or organic liquid used as vehicles for the preparation of solutions or suspensions in the synthesis of a new drug substance. Others may include extraneous contaminants that should not occur in new drug substances and are more appropriately addressed as good manufacturing practice (GMP) issues. The actual and potential impurities most likely to arise during the synthesis, purification and storage of a new drug substance should be described. The summary should include test results of batches manufactured during the development process and batches from the proposed commercial process, as well as the results of stress, used to identify potential impurities arising during storage. Any degradation product observed in stability studies at the recommended storage conditions at a level greater than the identification threshold should be identified. When identification of an impurity is not feasible, a summary of the laboratory studies demonstrating the unsuccessful effort should be included in the regulatory application.

The acceptance criteria of impurities should be based on Pharmacopoeial standards (U.S. Pharmacopoeia, European Pharmacopoeia and Japanese Pharmacopoeia) or any other known safety data. Analytical results should be provided in an application for all batches of a new drug substance used for clinical, safety and stability testing, as well as for batches representative of the proposed commercial process.

Qualification of impurities is the process of acquiring and evaluating data that establish the biological safety of an individual impurity or a given impurity profile at the level(s) specified. The level of any impurity present in a new drug substance that has been adequately tested in safety and/or clinical studies is considered qualified. Impurities that are also significant metabolites present in animal and/or human studies are generally considered qualified. In the absence of supporting safety data, genotoxicity tests along with acute and subchronic toxicity studies (based upon the intended use of the product) are conducted to demonstrate that the impurities at specific levels would not pose any hazards.

The reporting, identification and qualification thresholds for impurities are recommended in these guidances, based upon maximum daily dose of the drug. *For the*

*purpose of this chapter, only the dose less than 2g is referred.* For maximum daily dose of drug less than 2g (1) the identification threshold should be 0.1% or 2mg whichever is lower and (2) the qualification threshold should be 0.15% or 3mg whichever is lower.

The qualification of biological impurities such as peptides, oligonucleotides, radiopharmaceuticals, fermented and semi-synthetic products, herbal products and crude products of animal or plant origin are not covered under Q3A and Q3B guidelines. In the case of biologics, potential risks may be associated with host-cell contaminant derived from bacteria, yeast, insect, plant and mammalian cells that can result in allergic reactions and other immunological effects. For products derived from insect, plant and mammalian cells or transgenic plants and animals, there may be an additional risk of viral infections.

## ESTIMATION OF THE FIRST DOSE IN HUMANS

Extensive non-clinical data collected from a large number of acute and repeat-dose toxicity studies help determine the initial safe and maximum recommended starting dose (MSRD) and dose range for the Phase I human trials using healthy subjects (80–100) and identify any parameters for clinical monitoring for potential adverse effects (Guidance for industry, maximum safe starting human dose, July 2005). All the relevant preclinical data including pharmacologically active dose, the full toxicological profile and the PK/TK and ADME data of the therapeutic agent are considered when determining MSRD in the algorithmic process.

In calculation of MSRD, NOAEL is the major element tested in animal species. In order for conversion of NOAEL to human equivalent dose (HED), a species-specific conversion factor (conversion factor table described in the guidelines) is used. Although only NOAEL is used in the algorithm for calculating an MSRD, other data (exposure/toxicity, relationship, pharmacological data or prior clinical experience with related drugs) can affect the choice of most appropriate species, scaling and safety factors. The conversion should be based on the normalization of the doses to body surface area. The extrapolation of animal dose to human dose is done by dividing the NOAEL in each species by appropriate body surface area conversion factor (BSA-CF). This conversion factor is a unitless number that converts mg/kg dose of each animal species to the mg/kg dose in humans which is equal to the animal's NOAEL in mg/m<sup>2</sup> basis. The resulting value is HED and the species that generates

the lowest HED is considered the most sensitive species. The formula for HED calculation is shown below:

$$\text{HED} = \text{animal dose in mg/kg} \times (\text{animal weight in kg/human weight in kg})^{0.33}$$

In order to calculate MSRD, a safety factor (usually 10) is applied to HED in order to increase the assurance that the first dose in humans will not cause any adverse effects. However, it can be raised when there is reason for increased concern and lowered when concern is reduced because of available safe data.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

It is recognized that significant advances in harmonization of the timing of non-clinical safety studies for the conduct of human clinical trials for pharmaceuticals have already been achieved and are detailed in the referenced guidances in this chapter, and continued efforts are ongoing to maintain harmonization for pharmaceutical development globally. However, some differences still remain in a few areas. Regulators and industry will continue to consider these differences and work towards further improving the drug development process. In the last few years, a number of computation toxicology models have been developed (e.g., *in silico modeling*) as alternatives to *in vitro* and *in vivo* models and in efforts to reduce animal testing; however, computational testing has not been approved by regulators for pharmaceutical development at this time. Recently, FDA has developed an Informatics and Computational Safety Analysis program for future archiving of safety data, but at this time it is still a work in progress.

# Statistics in veterinary toxicology

Shayne C. Gad and Russell Barbare

## INTRODUCTION

Veterinary toxicology has seen a dramatic and consistent increase in available statistical resources in the past few decades. Currently, free resources locatable by web searches include formulae and examples for common statistical techniques, online or freely downloadable software to perform many common biostatistical analyses, sample data sets, statistical guides from governmental and private organizations and biostatistics course notes from multiple universities. What is not necessarily clear from any of the resources above or from many of the similar for-pay resources is that there is a framework or process for conducting or facilitating a quality statistical analysis. The more complete process is:

- 1 Define the objective of the analysis, i.e., "what is the question?"\*
- 2 Determine the types of data.\*
- 3 Identify constraints/limitations on the study data and analytical methods.\*
- 4 Generate preliminary graphs and summary statistics of the data.\*
- 5 Choose the correct technique based on items 1–4 above.
- 6 Perform the analysis.
- 7 Interpret the results and generate graphs and summary statistics of the significant results.

\*These steps are not strictly ordered.

All of these, or at least how they will be addressed, should be considered before a study is conducted. Following the complete procedure will increase understanding of the data and lessen the chance of making

mistakes. Unfortunately, detailed coverage of these steps would fill at least one and probably several books. A veterinary toxicologist should be able to perform some simple analyses based on this chapter alone, but our main purpose here is to provide an overview of the process with enough detail so that an investigator can evaluate and utilize other resources as needed, application of the approach are addressed in Gad (2008).

## Core concepts and vocabulary

### *Relationship between variables*

One of the most important concepts to understand is that statistics can never actually prove or disprove causation. Correlation, a statistical measurement of how strongly variables are related, is not causation no matter how strong the correlation is.<sup>1</sup> Statistics can instead show, to a reasonable and often definable degree of confidence, whether or not one or more variables are *related to*, *associated with*, or *correlated with* one or more other variables. The variable for the outcome of interest is called the dependent variable, while the other variables are called independent variables, a.k.a. predictor or explanatory variables. Variables that the investigator has control over are automatically independent variables. For example, independent variables for an antibacterial drug study could be animal species, gender, age, number

<sup>1</sup>Toxicologists who want a short introduction to causation reasoning should start with Austin Bradford Hill's classic paper "The environment and disease: association or causation?" (Hill, 1965).

per dose group and drug dosage. Measurements such as food consumption, animal weight, clinical observations, plasma bacterial counts and blood chemistry and hematology would be dependent variables in this example. The independent versus dependent distinction may seem blurry for retrospective analyses or data mining, where the investigator is picking data to analyze rather than reporting on an experiment. In such cases, decide on the outcome of interest first, and then the variables that measure the outcome of interest are the dependent variables while all other available data constitute the independent variables.

### Statistical significance and statistical error

When a finding is statistically significant at a probability of 0.05 or less, usually written as  $p \leq 0.05$ , the probability of random chance producing either the data seen or any more extreme data is 0.05, or 5%. The choice of a 95% level of confidence for declaring statistical significance is arbitrary but has immense historical inertia and regulatory enshrinement and therefore  $p \leq 0.05$  should be considered the default choice. Unfortunately, statistical significance is not always correlated with the existence of a real effect, as shown in Table 12.1.

A Type I error is called a false positive and the probability of a Type I error is indicated by  $\alpha$  (alpha). A Type II error is called a false negative but instead of having a symbol specifically for Type II error probability,  $\beta$  (beta) is used to indicate one minus the chance of a Type II error:  $\beta = 1 - \text{probability (Type II error)}$ . Beta is called power and can be read as the chance of finding no effect if there really is no effect. It should be clear that neither error is desirable. Fortunately, the two types of error can be controlled in a statistical analysis but there is an unavoidable tradeoff: as  $\alpha$  is decreased (less chance of a false positive) and  $\beta$  is increased (less chance of a false negative), the number of animals needed to find a specific effect size is also increased. Put simply, if the investigator wants less chance of making statistical errors or wants to discern smaller effect sizes, they will need to use more animals or other experimental units (such as cell culture units). The exact relationship between  $\alpha$ ,  $\beta$ , effect size and animal counts is different for differing statistical analyses, but good tools for calculating these exist online and in many software packages and textbooks. When in doubt, eqn (1) should be used as an estimator for interval dependent data.

$$n \geq 2s^2 \frac{(Z_{\alpha/2} + Z_{\beta})^2}{\Delta^2} \quad (1)$$

where:

- $n$  = number of required samples or animals in each test arm (roundup).
- $s$  = the expected standard deviation of the sample data.
- $Z_{\alpha/2}$  = the Z-statistic for the desired alpha. Technically, this is the value at which the cumulative standard normal distribution reaches  $1 - \alpha/2$ . Practically, since alpha is almost always 0.05, this value is usually 1.96.
- $Z_{\beta}$  = the Z-statistic for the desired beta. Most calculations use  $\beta = 0.80$  ( $Z_{\beta} = 0.842$ ) or  $\beta = 0.90$  ( $Z_{\beta} = 1.282$ ).
- $\Delta$  = the expected difference in effect size between groups.

This can be read as “In order to find a difference of  $\Delta$  or more between groups, with a false-positive rate of no more than  $\alpha$  and a false-negative rate no more than  $1 - \beta$ , and assuming the sample standard deviation will be no more than  $s$ , then at least  $n$  animals per group are required.” Since both  $s$  and  $\Delta$  in the equation are squared,  $n$  inflates rapidly as standard deviation increases or the desired effect criterion (difference) decreases.

The question of the relevance or meaning of statistical significance is also complicated by considerations of biological significance. Biological significance generally means a change or condition that could appreciably affect the health of an animal (in humans, “clinical significance”). To understand how the significances can be distinct, consider a study where each animal has a number of blood samples drawn over a period of time but care is taken that the total volume of blood taken will not significantly affect animal health. Because of the repeated blood sampling there are real decreases in the red blood cell-related parameters such as hemoglobin and hematocrit and the changes are consistent enough that statistical analysis of the time trends will usually find these changes. However, neither the real hematological changes nor the statistically significant findings mean the changes are biologically significant. Therefore, a statistic is not a substitute for sound professional judgment but in order to make intelligent conclusions veterinary toxicologists should be aware of the difference between the existence of a real effect, finding such an effect statistically and the biological significance of an effect.

TABLE 12.1 Possible types of statistical error

		Was the result statistically significant?	
		No	Yes
Is there a real effect?	No	No error	Type I error
	Yes	Type II error	No error

### Degrees of freedom

Most statistical methods produce or refer to a measure called degrees of freedom (df). The degrees of freedom are the number of levels of each independent variable that are not fixed by the calculation. The usual

illustration is that if there are  $N$  observations and the mean of the observations is known, then  $N - 1$  of the observations can be anything but one of the observations is constrained because the means formula has to come out to the known mean. The degrees of freedom in the example is therefore  $N - 1$  because that is the number of non-fixed or free observations. Degrees of freedom is a very important statistical concept, but practically, it is not an intuitive concept for most people and software will normally handle the df calculations without intervention so there is no pressing reason to understand the concept unless the toxicologist is studying statistics.

## OBJECTIVE OF THE ANALYSIS

Statistical methods generally perform some combination of three functions:

- 1 The most commonly employed function is hypothesis testing. Examples of hypothesis testing include determining if groups of data are different from each other or deciding if an agent has a significant effect on a specified outcome.
- 2 A second function is building statistical models which may then be used for predicting the outcomes of experiments not previously performed or improving disease diagnosis and treatment. A statistical model is simply a set of mathematically defined relationships between the treatment and response aspects (variables) in the study that show both the types of relationships, e.g., linear, and the strengths and best estimates of the relationships.
- 3 The third function, reduction of dimensionality, has the goal of reducing the number of variables in a statistical model without significant reduction of information. Less complex models are desirable because they are easier to understand and make predictions from. The production of descriptive or summary statistics is the second most commonly utilized statistical function in toxicology and can be considered a subset of reduction of dimensionality. In general most descriptive statistics are some measure of central tendency, such as a mean or median, plus some measure of variability, such as standard deviation or range (minimum and maximum). The inclusion of summary statistics as a subset of reduction of dimensionality is common in toxicology literature but statistical literature considers these two separate functions and usually refers to reduction of dimensionality as dimension reduction.

## TYPES OF DATA

The types and quantities of available data limit what statistical techniques are valid so it is important to characterize both the independent and the dependent variables. Variables can in general be one of:

- Interval, a.k.a. continuous: the variable can take on any value within a range of numeric values. Examples include body weights or blood chemistry readings.
- Categorical: the variable can only take on a limited number of values and the categories have no intrinsic order. Examples include gender or species.
- Ordinal, a.k.a. ranked: the variable can take on a limited number of values but there is some intrinsic order to the values. Examples include growth stage for male horses (foal, colt or stallion) or the Draize scale for irritation ([Draize, 1959](#)).

One important subtype of variable is the binary variable, i.e., a variable that can take only one of two values. Gender is the classic binary variable in biological sciences. Both categorical and ordinal variables that can only take two values should be analyzed as binary variables. Therefore, all independent and dependent variables should be classified as one of interval, binary, categorical or ordinal. When deciding on variable classification, the investigator must take care to distinguish between what values are possible for a variable and how they are measured. For example, imagine a study that classified animals as underweight, nominal weight or overweight but did not record the actual weights. Normally body weight is an interval variable but in that case, it would be an ordinal variable because the only measure of body weight is one of three ranked classes.

## Changing the data

Occasionally data need to be changed before analysis. Common types of changes include coding ordinal values, imputing values, transformations and removal of outliers.

### *Coding ordinal variables*

Because of their nature, ordinal variables often have to be renamed before analysis because both the value of the variable and the order in relationship to other values has to be evaluated correctly. In the example for growth stages for male horses above, a veterinarian would recognize the inherent order foal→colt→stallion but a machine would alphabetize the terms and order them as colt→foal→stallion. Therefore ordinal variables are

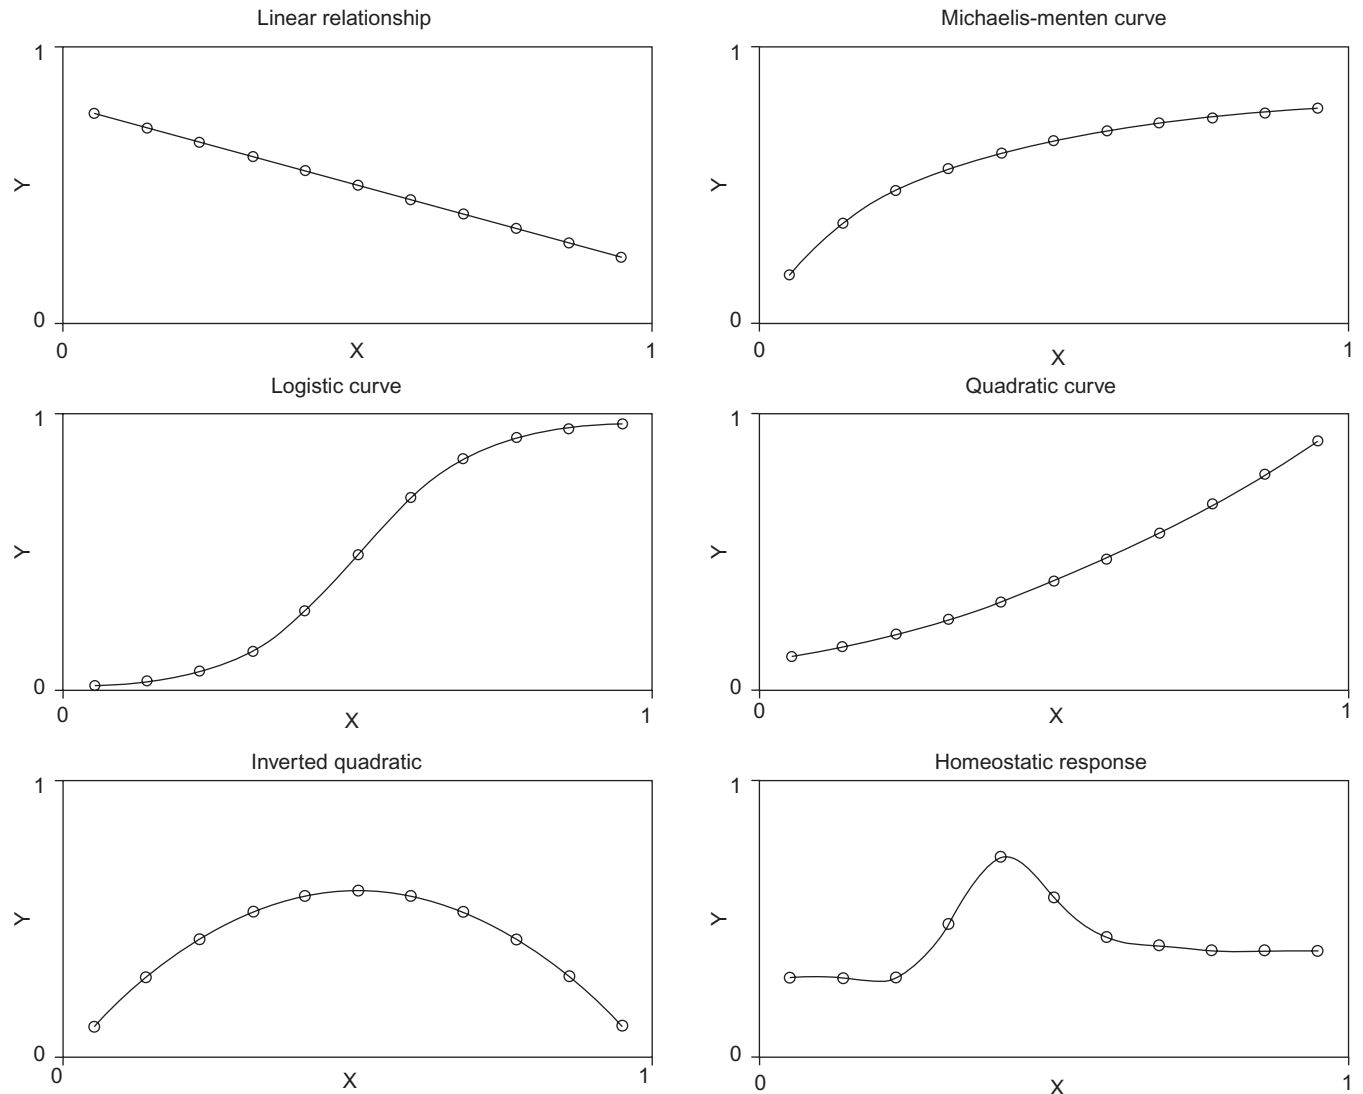

FIGURE 12.1 Idealized relationships between independent and dependent interval variables.

often renamed to either the series 1, 2, 3...or the series A, B, C...before analysis so that the software automatically recognizes the proper order. This renaming is called coding.

### Imputation

Statistically speaking, imputation is the assignment of values to censored observations. There is some historical precedent for imputation but the practice has never been statistically valid and is not recommended.

### Transformations

As seen in Figure 12.1, the relationship between the independent and dependent variables can be many shapes besides linear and, indeed, truly linear relationships

between variables over their full range of possible values are vanishingly rare. Therefore, it is often tempting to transform the data before analysis to make the relationship linear, thereby making both the calculations and the interpretation easier. The necessity of transformation before analysis has decreased over time because valid statistical techniques for a variety of variable relationships have become more available, but there is still both some historical impetus towards linearizing data and the occasional data set for which transformation is desirable. Generally, transforming data is rarely necessary for valid analysis, but may be reasonable if (1) there is a valid statistical, regulatory or other reason to use a transformation rather than a different statistical technique on untransformed data and (2) the transformation method and criteria for using it is decided before the data are analyzed further.

Common transformations circumstances in toxicology include:

- In cases where repeated samples are taken from an animal over time it is common practice to subtract the baseline value or mean of the baseline values from post-exposure samples so that results can be read as change from baseline. This is a reasonable transformation, but there are minor statistical objections and modern analysis methods generally make this unnecessary.
- For studies that dose by absolute dose amount, transforming drug dose to dose per body mass, e.g., replacing  $\text{mg}_{\text{drug}}$  with  $\text{mg}_{\text{drug}}/\text{kg}_{\text{body\_mass}}$  as an independent variable, is recommended. In virtually all cases, individual dose per body mass will fit models closer than absolute dose.
- A valid statistical reason to transform data is heteroscedasticity, meaning the variability of the dependent variable is not the same for each observation. Most statistical models assume that variance (amount of variation) is the same for all observations but, realistically, variance for many biological measurements increases with the magnitude of the measured value. This increase is known as variance inflation. Figure 12.3 illustrates heteroscedastic variance inflation in that the range of values increases significantly from group A to group C. If the investigator knows or suspects that heteroscedasticity exists, two good general methods for variance stabilization are Tukey's Ladder of Powers (Tukey, 1977) and the Box-Cox transformations (Box and Cox, 1964). The choice of which to use is primarily based on which is available in the analysis software. Both transformations are intended for the case of a single dependent interval variable where the magnitude of the variance is roughly proportional to the magnitude of the dependent variable.
- One common transformation example arises from pharmacokinetic calculations, where both area under curve (AUC) and maximum observed value ( $C_{\text{max}}$ ) values for the majority of species and studies are approximately lognormal distributed, which is visible when graphed (see Figure 12.6) and also leads to variance inflation in higher parameter values. Therefore it is recommended to take the logarithm of AUC and  $C_{\text{max}}$  values before analysis.

### Outliers

The term outlier applies to individual data points that are well outside the expected range of the data and usually only applies to dependent variable values. Outliers can occur in categorical or ordinal data but the term is usually applied to interval data. Under the assumption that interval data are normally distributed, i.e., follow the classic bell-shaped curve, about 68% of the values

will be within one standard deviation from the mean, about 95% of the values will be within two standard deviations and about 99.7% of the values will be within three standard deviations. Many box plots will indicate outliers as single points outside of the contiguous boxes and lines and this is the reason box plots may be preferable over scatter plots. Outliers are undesirable because they increase calculated variability disproportionately and may bias estimates of means. However, removal of outliers is only valid if the outliers are clearly documented experimental errors.

## IDENTIFYING CONSTRAINTS

Even after the types and quantities of data have been identified there still may be more than one appropriate statistical analysis. Other considerations can limit the list of reasonable or possible analysis methods and can also change the interpretation of statistical results, even if there is only one sensible statistical technique. Therefore, identifying other possible restrictions should be a fundamental part of any analysis. Common constraints for toxicology analyses and reasonable responses to the constraints are as follows:

**Constraint:** Biological, financial, temporal, logistical, and other practical realities limit the amount and types of data that can be taken. For example, it is not reasonable to get multiple closely spaced blood samples from small animals (biological limitation), to get a large number of organ samples from large animal species (financial limitation), to reliably estimate background tumor incidence in any species in less than the majority of the species' lifetime (temporal limitation) or to use sufficient numbers of animals of exactly the same age and source to power a chronic toxicity study as one would a Phase III clinical study.

**Response:** Smart study design can mitigate many of these problems. Practically, this means using designs that are already well tested and well understood. Such designs can be found in toxicology literature and other publications and established toxicology labs will have outlines for such studies. Operational limitations also require careful interpretation and the investigator should use professional judgment when deciding how generally or specifically the conclusions apply.

**Constraint:** Data sets are often small, from heterogeneous populations, inconsistently measured, or not necessarily from the population of interest. These factors are grouped together because they interact, so a designed study controls population homogeneity and measurement consistency, but is often small due

to financial or other operational constraints. Also, designed studies may not be reasonable to perform in the population of interest. On the other hand, research and data mining may yield larger data sets from the population of interest at the price of increased uncertainty in measured values.

**Response:** This is usually an interpretation problem, as noted above. If the investigator wants to analyze results across multiple studies or from multiple data sources then they should explore the field of meta-analysis.

**Constraint:** Regulatory agencies may have preferred statistical methods for certain studies. Similarly, professional organizations or publications may have favored statistical methods due to professional consensus or even historical inertia.

**Response:** The method suggested by the regulatory or professional organizations should be used unless there is compelling evidence that the suggested analysis would be invalid.

**Constraint:** Most commonly the investigator is examining a minutely small fraction of the animal population, but with endangered species, rare breeds and similar cases it may be possible to collect data for a significant fraction of the species of interest.

**Response:** In the latter case, there are more accurate methods to calculate some summary statistics and to perform some statistical analyses, but the methods are different than those presented in beginning biostatistics courses. There is nothing wrong with using standard statistics, but if the investigator wants increased precision then they should examine sampling statistics.

**Constraint:** Study design for designed studies, or data collection design for data mining, can determine which statistics are valid. For example, relative risk, a.k.a. risk ratio, is not a valid statistic for case-control studies and many retrospective studies on comparative incidence rates, even though it is technically calculable. Odds ratios are valid in such cases.

**Response:** Relative risk is the most common biostatistic that can be invalidated because of study design. In general, if the investigator wants to model or perform hypothesis tests about comparative incidence rates, relative risks or similar topics, then they should learn more about categorical data analysis, which includes analysis of such data.

**Constraint:** If both the dependent variable and the independent variables are all binary, ordinal or categorical, then the amount of data can be a deciding factor in the choice of analysis. This happens because many analysis methods for such data are based on approximations that only become valid for a sufficient volume of data.

**Response:** Count the number of animals or observations for each unique combination of the variables. Tables are the best way to do this. The cutoffs where different methods should be used depend on the statistical test

and are therefore covered in the section on exact tests and chi-square tests below. Alternatively, the investigator can group categories together to get sufficient numbers per category.

**Constraint:** Data are often censored by circumstances other than an investigator's design. In this case, censoring means not all the data could be collected as desired. Common censoring circumstances include animal death or debilitation, spoiled samples such as coagulated blood samples, skipped experimental procedures or, in the case of retrospective analysis, imperfect access to records.

**Response:** If data were censored at random then censoring is not a serious limitation because statistical techniques that work for censored or unbalanced data have been developed. "At random" in this case means that the pattern of data loss has no relationship to the values of the independent or dependent variables. However, if the censoring is related to the values of other variables, then inference on those variables is potentially biased after the censoring occurs. In the latter case, the only statistically analyzable dependent variable is time to censoring.

Limitations caused by censoring deserve some additional explanation. Consider a group of animals given a substance that severely inhibits red blood cell (RBC) production. The animals with dangerously low RBC values will die or be taken off study *in extremis*. Therefore, group mean RBC values are only representative of dosed animals *before* any animals are taken out of the study. Any statistics afterward are biased because the worst case(s) were eliminated from consideration. Therefore RBC values cannot be used as a dependent variable because they are inherently biased and the amount of the bias cannot even be reliably estimated. If there are enough deaths or removals *in extremis*, then the times to removal can be analyzed as the dependent variable and the relationship between the independent variables and time to removal can be estimated. However, there is a broad gap between theory and practice. The statistical theory says that even one death that may be related to the effects being studied makes time to death the only valid dependent variable, but if that criterion were applied rigorously, then a large proportion of studies would be unanalyzable. More practical guidelines are:

- All censoring must be clearly documented.
- Possible reasons for censoring must be investigated and also documented.
- If the censoring has no relationship or no clear relationship to the values of the dependent or independent variables then proceed with analyses as planned.
- If the censoring has a clear relationship to other variables' values then time-to-censoring is the only valid

dependent variable for the whole study but the portion of the study before censoring occurs may be analyzed as planned as long as the demarcation is clearly documented. Proceeding with the planned analysis but reporting that censoring may have biased the results is also common and not unreasonable as long as the possible bias and reason for it is reported in all study results.

Time to death analysis, also called survival analysis, is a subset of time-to-event analysis. One common category of toxicology studies that includes both survival analysis and time-to-event analysis is carcinogenicity studies.

## GRAPHING AND SUMMARIZING DATA

Examining data graphically *before* analysis is often underemphasized and all too rarely employed. To understand why this might be significant, consider that one of the best analysis tools where the dependent variable is interval data and the independent variables are mixed interval, binary and/or categorical data is Analysis of Variance (ANOVA). Now assume that the actual data are fairly close to the idealized relationships shown in [Figure 12.1](#). Which relationships will ANOVA produce correct results for? The answer is: only the linear relationship. ANOVA will probably find the first quadratic, the Michaelis-Menten curve and the logistic relationships to be statistically significant, but will estimate the best fitting straight line, entirely missing the curvature. ANOVA will estimate no relationship between the independent and dependent variable (flat line) for the inverted quadratic relationship and may or may not find significance for the homeostatic curve despite the existence of strong relationships. Therefore, if the analyst does not graph the variables before analysis, then serious errors can be made even when using a powerful, well-accepted technique. If the analyst does graph the relationship first, then inclusion of a single quadratic term will produce a valid analysis of both the linear and quadratic cases and closely approximate the Michaelis-Menten curve. The other two cases require more advanced techniques. Note that only the inverted quadratic relationship is unlikely because close approximations of all the others can be found in toxicologic data.

The suggested graphs for various types of variables are shown in [Table 12.2](#). These are by no means the only possible graphs but are well accepted and unlikely to lead to serious misrepresentation of the data. Bar graphs are often referred to as bar charts and boxplots may be called box and whisker plots or just box plots. [Figures 12.2–12.4](#) show an example bar graph, boxplot

and scatterplot, respectively. Other example scatter plots are shown in [Figure 12.5](#). Toxicologists who want to further explore good data presentation techniques could start with Edward Tufte's classic *The Visual Display of Quantitative Information* ([Tufte, 1983](#)).

Along with the generation of initial graphs, some summary statistics for both the dependent and independent variables should be generated before analysis. Two general guidelines for summary statistics are:

- Interval variables should generally be summarized by mean, standard deviation, range (minimum and maximum) and count (number of animals or observations). Interval variables that are far from normally distributed should be summarized by median, quartiles (values that identify the boundary for the lowest and highest quarters of the data), range and count.
- Binary, categorical or ordinal variables should be summarized by tables of how many animals or observations fall into each unique combination of variables.

Initial summary statistics are primarily supposed to be an aid to understanding and another way of avoiding analysis errors. Therefore, initial summaries should use a reasonable minimum of statistical calculations and should be presented in a clear format. Example tables can be found in professional publications and many organizations will have example reports with tables or templates for generation of summary statistics.

Survival and time-to-event analyses use a life table to summarize data. An example life table is shown in [Table 12.3](#). The failures column indicates the number of animals developing the disease or condition of interest during the given time interval. The censored column shows the number of animals who died or were removed from the study and is unrelated to the number failing. Conditional failure probability is calculated as  $(1 - \text{failures}/(\text{at risk}))$  for each age category and cumulative failure is the cumulative multiplication of the conditional failure. The conditional and cumulative failure avoid counting censored animals, so, for example, even though over 50% of the population is gone by age 65–70, the failure rate does not go over 50% until age 70–75. Plotting the cumulative failure in a stepwise fashion and adding markers for the censored animals results in a Kaplan-Meier graph ([Kaplan and Meier, 1958](#)), which is the fundamental graphical tool for survival analysis.

Once the graphs and summary statistics are generated, the investigator should examine variables for differences related to a single variable, usually called main effects, and differences related to pairs of variables, usually called interactions. Common main effects unrelated to treatment are: animal weights vary by gender, breed and life stage; and normal hematology, blood chemistry and urinalysis values are somewhat different by gender and breed.

TABLE 12.2 Suggested graphs based on data types

Dependent variable(s) <sup>1</sup>	Independent variable(s) <sup>1</sup>				
	Single variable			Multiple variables	
	Continuous	Binary	Categorical or ordinal	Continuous	One or more continuous plus one binary, categorical, or ordinal
<b>Single variable</b>					
Continuous	Scatterplot	Scatterplot or boxplot <sup>2</sup>	Scatterplot or boxplot <sup>2</sup>	Separate graphs <sup>3</sup>	Scatterplot of means <sup>4</sup>
Binary	Scatterplot or boxplot <sup>5</sup>	None <sup>6</sup>	Bar graph or none <sup>7</sup>	Separate graphs <sup>3</sup>	Boxplot <sup>8</sup>
Categorical or ordinal	Scatterplot or boxplot <sup>5</sup>	Bar graph or none <sup>7</sup>	Bar graph or none <sup>7</sup>	Separate graphs <sup>3</sup>	Boxplot <sup>8</sup>

Continuous	Scatterplot <sup>9</sup>	Boxplot <sup>9,10</sup>	Boxplot <sup>9,10</sup>	Separate graphs <sup>11</sup>	Separate graphs <sup>11</sup>

## Notes

<sup>1</sup>Independent variables are graphed on the X (horizontal) axis and dependent variables are graphed on the Y (vertical) axis. In variable combinations other than those listed, first separate the variables so that they fit one of the existing categories.

<sup>2</sup>Vertical boxplots, each box represents a single level of the independent variable.

<sup>3</sup>Separate by the independent variables and graph accordingly.

<sup>4</sup>Separate means for each level of the binary, categorical or ordinal variable, connected by lines. Consider putting in error bars.

<sup>5</sup>Horizontal boxplots, each box represents a single level of the dependent variable. For scatterplots, point markers identify levels of the dependent variable.

<sup>6</sup>This case can be clearly represented by a table; a bar graph rarely adds significant value.

<sup>7</sup>Tables are also illustrative in this case. In general, relatively small values should use tables; larger values should use bar graphs. For bar graphs, both independent and dependent variables show on the X-axis, grouped by the dependent variable, and the Y-axis represents counts for each category.

<sup>8</sup>Separate horizontal boxplots for each unique combination of independent and dependent binary, categorical and ordinal value, grouped by the dependent variable value.

<sup>9</sup>If the dependent values are on the same scale, a single graph is possible using different point markers to identify separate dependent variables. Otherwise use separate graphs for each dependent variable.

<sup>10</sup>Vertical boxplots, each box represents a single independent variable.

<sup>11</sup>Separate by both the dependent and independent variables until the case matches a group listed here and graph accordingly.

**FIGURE 12.2** A sample bar graph illustrating the number of responders grouped by the ordinal variable group and the binary variable gender. Potentially useful variations include showing percentage of responders instead of numbers or stacking the bars to show proportions of a whole.

Common main effects related to increasing drug exposure, called the three dimensions of dose response, are: increased proportion of responders, increased severity of response and decreased time to response and/or faster response progression. For graphs of an independent variable versus a dependent interval variable, examine the shape of the relationship and refer to [Figure 12.1](#) and

the discussion on it. Approximately linear relationships can be well modeled by the techniques discussed here, shapes with curvature in only one direction can usually be well modeled by including a quadratic term in the model, S-shaped curves can be modeled using logistic regression, but shapes with complex curvature require more advanced techniques.

**FIGURE 12.3** Boxplots are relatively information dense. The box extends to the lower and upper quartiles (the values which 25% and 75% of the data fall below, respectively). The capped lines extend to the minimum and maximum in some plots but for this one they extend to the 5% and 95% percentiles (the values which 5% and 95% of the data fall below, respectively). The line in the box is the median and the circle in the box is the mean, while the squares outside of the boxes represent outliers (values far enough from the mean or median to be considered unusual). Note that capped lines in other graphs indicate the standard deviation of the data rather than the range.

**FIGURE 12.4** An example scatterplot showing white cell count in relation to drug dose, with the muscle irritation score as the point symbol.

An interaction means the relationship between one independent variable and the dependent variable depends on the value of another independent variable. Common interactions in toxicology include: the shape of a dose-response curve may depend on gender, tumor incidence increases dramatically with both carcinogen exposure and the presence of oncogenes, and drugs that compete for binding sites have non-additive effects when coadministered. Both metabolic induction and inhibition can also produce interaction effects and the

timing of the interaction depends on how fast induction or inhibition happens. When interaction appears to be present, an interaction term should be put into the statistical model. Figure 12.5 shows the difference between no effect, a main effect and a main effect with interaction. Interactions without main effects are less common but if an interaction is present then the main effects must remain in the model.

Graphing and summarizing the data before analysis is in conflict with pure statistical theory. One of the

TABLE 12.3 Example life table

Animal age (months)	# at risk	Failed	Censored	Conditional failure probability	1-(Cumulative failure estimate)
00-01	100	2	1	0.9800	0.9800
01-05	97	1	0	0.9897	0.9699

30-35	92	1	2	0.9891	0.9294
35-40	89	3	1	0.9663	0.8980
40-45	85	3	2	0.9647	0.8664
45-50	80	5	3	0.9375	0.8122
50-55	72	5	5	0.9306	0.7558
55-60	62	2	9	0.9677	0.7314
60-65	51	0	13	1.0000	0.7314
65-70	38	8	6	0.7895	0.5774
70-75	24	12	0	0.5000	0.2887
75-80	12	1	6	0.9167	0.2647
80+	5	2	3	0.6000	0.1588

absolute rules of statistics is that you cannot change the analysis methods or goals just because you do not like the first answer. However, there is often more than one valid analysis method and there is no guarantee that two or more valid methods will produce the same results, so choice of method can influence results. Even single analysis methods usually have details that can be tweaked in various ways that may alter the results. Since an experienced analyst can at least guess at some answers by looking at graphs or even at raw data, this implies that analysis methods should be set before seeing *any* of the data, because otherwise a biased analyst could pick the analysis method or method details based on the outcome they wanted to show. The ideal of setting the exact analysis before reviewing the data should be the goal for all statistical analyses and is approachable for well-controlled studies with experienced investigators and analysts but practical experience suggests that newer investigators will make more and worse mistakes by not doing a preliminary examination of the data first. The controls that should be put in place and followed rigorously are:

- The overall goal (modeling or hypothesis testing) must be decided first.
- For hypothesis testing the question, the variables that will be included in the model and the allowable  $\alpha$  must be decided first and not changed. For model building, all procedures and cutoffs must be fixed prior to analysis.
- All main effects and any interaction or quadratic effects the investigator suspects are possible should be tested or put into the initial model. Note that

constrained study designs may make testing of some specific interactions impossible.

Occasionally, a study does need to be reanalyzed. In that case, the second analysis should be performed by a different person than the first and the second analyst should be told as little as reasonably possible about the first results. Investigators who want further information should look into blinding or, more generally, principles of study design.

## CHOOSING APPROPRIATE TECHNIQUES

### Parametric versus non-parametric tests

Statistically speaking, the term parametric means the data are assumed to follow a known distribution, usually the normal distribution, while non-parametric means no distribution is assumed. Many statistical tests on dependent interval data have the assumption that the data are normally distributed after adjustment for other model parameters. However, excessive outliers, heteroscedasticity that transformations cannot ameliorate and a few other circumstances can violate this assumption. Moderate departures from normality have little effect on most recommended biostatistics analyses but large deviations can invalidate the results. Therefore, if the investigator finds uncorrectable heteroscedasticity, a larger than expected proportion of outliers, or simply suspects that interval data are non-normal, then they

**FIGURE 12.5** In the first panel, gender has no effect on response, i.e., the dose response (slope and intercept of the best-fit line) is approximately the same for both genders. In the second panel, gender has a main (additive) effect on response. In the third panel, gender and dose interact – the relationship between dose and response depends on gender.

should test to see if the data can be treated as normal for analysis. Graphical analysis can help make this decision but caution is advised. The standard graph for visually examining the distribution of a single variable is the histogram, which shows the data values on the X-axis and the data frequency (count or percentage) on the Y-axis. Figure 12.6 shows three histograms with simulated data from known distributions. Panel one shows data actually drawn from the normal distribution. Unfortunately, normality is not obvious by visual examination. The second panel in Figure 12.6 may look vaguely normal but is actually bimodal.

**FIGURE 12.6** The data in the first panel are random normal with mean 10 and standard deviation 3. The data in the second panel are bimodal, i.e., having two peaks instead of one. Bimodality is common in some blood chemistry readings, e.g., hemoglobin count for males (higher peak) and females (lower peak). Panel three shows data from a lognormal distribution, showing its characteristic asymmetry – more higher values than would be expected from a true normal distribution.

Reasonable tests for normality include Levene's test (Levene, 1960), the Brown-Forsythe test (Brown and Forsythe, 1974) and the Breusch-Pagan, a.k.a. Cook-Weisberg, test (Breusch and Pagan, 1979). Exact choice of test depends on both test availability and the model used. If the test rejects normality then the analysis method should be changed from a parametric method to a nonparametric method (see Table 12.4). Parametric methods are more powerful than nonparametric methods when the data are close to normal but in the cases

TABLE 12.4 Suggested hypothesis testing procedures

Dependent variable(s)	Independent variable(s)				
	Single variable			Multiple variables

Interval, parametric data	MANOVA	MANOVA	MANOVA	MANOVA <sup>c</sup>	MANOVA

<sup>a</sup>ANOVA in this case is the same as linear regression, but the statistics will be presented differently.

<sup>b</sup>Special cases: If there are two samples each from a single animal, use a paired *t*-test. If the two groups have significantly different variances, use Cochran's *t*-test.

<sup>c</sup>The best readily available test but not the best overall test – treat the ordinal variable as categorical.

<sup>d</sup>See discussion of Fisher's exact test and chi-square tests to decide which is appropriate.

<sup>e</sup>Not all software packages extend the exact test beyond the  $2 \times 2$  case. If not, combine groups until Fisher's or chi-square can be used.

<sup>f</sup>See separate discussion of Cochran-Mantel-Haenszel statistics.

listed above nonparametric methods are less likely to produce incorrect results.

## Balance

For studies that divide animals into groups or cohorts, even numbers in each group are preferable. This is referred to as balanced group assignment and increases power. However, all of the analysis methods mentioned are valid for moderately unbalanced group numbers.

## Repeated-measures analysis

Body weights and other readings and samples taken from the same animal over time are referred to as repeated measures. Common repeated measures are weight, vital signs, blood chemistry and hematology, and urinalysis values. The preferred techniques for analyzing repeated-measures data is an extension of ANOVA called repeated-measures mixed-model ANOVA, also known as longitudinal analysis. Readings taken close together will be numerically close to one another, especially for slowly changing measures such as animal weights. The term for this is auto-correlation. Therefore, these repeated readings cannot be considered independent samples (or readings), which is a problem because most statistical methods assume sample independence. Repeated-measures ANOVA estimates auto-correlation and thereby improves the estimation of other effects.

## Trend analysis

Trend analysis is a loose grouping of techniques that attempt to determine if there is a consistent relationship between two variables, i.e., as one variable's values increase, the other variable's values consistently increase or decrease (without reversals). Statisticians refer to this type of relationship as monotonic. The simplest monotonic relationship is a linear relationship but shapes such as the logistic curve and Michaelis-Menten curve are also monotonic. Common monotonic trends in veterinary toxicology are body weights of healthy animals, which typically increase over time, treatment response rates, which usually rise with increasing dose, and tumor incidence rates, which usually increase both over time and with increased carcinogen exposure. ANOVA and its many variants are tests for linear trends for interval data and logistic regression is a trend test for proportion of animals responding to treatment based on dose where response is measured as either present or absent. For a 2-by-*k* table, where *k* > 2, the Cochran-Armitage trend test (Cochran, 1954; Armitage, 1955) is recommended. Most of the more advanced trend analyses for toxicologists arise from carcinogenicity studies and three good discussions of this topic are the Food and Drug Administration's guidance on rodent carcinogenicity studies (FDA, 2001), Crowley and Breslow's *Statistical Analysis of Survival Data* (Crowley and Breslow, 1984), and Peto *et al.*'s work for the World Health Organization on carcinogenicity screening (Peto *et al.*, 1980).

## Complex curves

Complex curves such as the Michaelis-Menten curve and the homeostatic response shown in [Figure 12.1](#) can be analyzed using methods that are generally referred to as nonlinear modeling. Pharmacokinetic modeling and estimation of enzyme effects are also naturally nonlinear models. Proficiency with nonlinear models is not common even among biostatisticians but software packages that are designed to correctly analyze pharmacokinetic data include WinNonlin and NLME ([Pharsight, 2010](#)) and acslX ([AEgis, 2010](#)).

## Final choice of hypothesis testing procedure

The exact hypothesis testing method should be selected from [Table 12.4](#) based on variable types and all other considerations mentioned so far. The tests listed are not the only valid tests but are in general robust (resistant to mild departures from assumptions), well accepted and available in virtually all statistical software packages. In more complex cases, consider dividing the data set until it matches one of the cases listed. In cases that are not covered and the situations listed as “Nothing recommended,” consultation with a biostatistician is recommended.

## PERFORMING THE ANALYSIS

The actual methods employed may depend on the chosen software package. Many of the indicated tests can also be performed online, are integrated into software such as Lab Information Management Systems (LIMS) and can even be programmed into a spreadsheet. All of these tests are also available in R ([R Development Core Team, 2008](#)), an open-source statistical analysis package. As a cautionary tale, note that the authors have performed statistical validation on three LIMS and in each case some deviations from validated answers were found. Therefore, if the investigator is using anything other than validated statistical software then the results should be confirmed by two or more sources.

## Hypothesis testing

A hypothesis test chooses between an initial assumption, called the null hypothesis, usually symbolized  $H_0$ , and an alternate assumption, usually  $H_A$  (sometimes  $H_1$ ). In general  $H_0$  is always the hypothesis of no significant relationship while  $H_A$  is the hypothesis of some relationship. The exact form of the relationship depends on the

test run; for example, a test for linear trend could state  $H_0$  as “there is not a linear relationship between  $X$  and  $Y$ ” and the matching  $H_A$  would say something similar to “there is a linear relationship between  $X$  and  $Y$ .” The goal of a hypothesis test is to determine if there is sufficient evidence based on the data to reject  $H_0$ . The pre-determined alpha is the “sufficient” boundary, so if the data fitted to the model are less likely than alpha, then the investigator rejects  $H_0$  and accepts  $H_A$  (generally, that there is a difference). When performing hypothesis testing it is important to understand the assumptions and limitations of the statistical method used. In the example above, a test for linear trend would not necessarily detect more complex relationships.

When selecting a hypothesis, the investigator should decide whether the test should be one-sided or two-sided, a.k.a. one-tailed or two-tailed. One-tailed tests answer questions like “is drug  $Z$  at least as effective as drug  $Q$ ,” “is the tumor incidence higher for exposed animals,” or “is disease progression slower in treated animals.” Two-tailed tests answer questions such as “is blood glucose different for treated animals,” “does treatment  $W$  have equivalent cure rates to treatment  $J$ ,” or “are bacterial mutation rates comparable to controls.” More formally, both a one-sided and a two-sided test have a null hypothesis similar to “ $A = B$ ” but  $H_A$  for the one-sided test will be “ $A > B$ ” or “ $A < B$ ” (one or the other, not both) while  $H_A$  for the two-sided test will be “ $A \neq B$ ” without distinguishing between  $A > B$  and  $A < B$ . When in doubt, use a two-tailed test.

A central consideration in hypothesis testing is control of the chance of false positives. For example, most blood chemistry and hematology panels have 30 or more individual readings. Assuming the investigator tests each reading for statistical significance at  $\alpha = 0.05$ , the actual chance of getting at least one false positive is  $1 - (1 - \alpha)^{30}$ , or about 79.5%. This is called alpha inflation due to multiple comparisons and whether this is acceptable depends entirely on non-statistical factors. For studies on drugs and medical devices, efficacy should be tested with a single measure at  $\alpha = 0.05$ . Both regulatory agencies and professional journals strongly resist accepting studies that performed efficacy tests until the tests showed a positive answer and doing so is statistically invalid. It is reasonable to have secondary efficacy or effect tests, but the study design should specifically state which test is primary and which are secondary. If more than one efficacy test has to be performed, then alpha can be adjusted so that the overall false-positive rate remains at 0.05 or less. The opposite situation applies to analysis of safety information, i.e., in general, all safety parameters are tested at  $\alpha = 0.05$  and all significant results are reported even though this inflates the false-positive rate. One way of understanding this dichotomy is to note drugs or other treatments

frequently have only one intended positive effect so it is important to be certain the positive effect is real but drugs and treatments usually have multiple side effects and it is important to identify all of them. Note that multiple comparisons also inflate the overall false-negative rate but that the false negative rate is rarely controlled.

Reduction of dimensionality may or may not be performed before hypothesis testing – either way is valid as long as the choice is made before analysis. In practice it is seldom done simply because it is an extra unnecessary calculation. When reduction of dimensionality is performed for hypothesis testing it is usually a one-step process where the decision is whether or not covariates, quadratic terms and interaction terms (all terms covered later) should be included in the model or not.

### *Analysis of survival and time-to-event data*

Tests for survival data and time-to-event data are somewhat different than the methods presented in Table 12.4. Common toxicology applications requiring these tests are times to death, tumor occurrence or serious toxicity. For such applications, the dependent variable is the time to the event of interest. Two common tests for survival analysis are the log-rank test (also log rank or logrank) (Mantel, 1966; Peto and Peto, 1972) and the Cox Proportional Hazard test (Cox, 1972). The log-rank test is a simple comparison of two groups while the Cox Proportional Hazard test is capable of handling mixed interval, binary and categorical data as independent variables.

Assumptions and limitations:

- The log-rank test gives the same weight to all calculations over time, even though earlier events are often of more interest. There is a variation called Peto's log-rank test (Peto and Peto, 1972) which weights earlier observations more.
- Hazards between groups in the Cox model are expected to be proportional, i.e., the survival curve for one group is a simple multiple of the survival curve for another group. However, an investigator who suspects non-proportionality based on the survival curve can include a time term in estimation that partially overcomes this limitation.

### *ANOVA and ANCOVA*

ANOVA is essentially the same as linear regression. The statistics are often presented somewhat differently, but the underlying assumptions are identical. Similarly, Analysis of Covariance (ANCOVA) is simply ANOVA with the inclusion of additional independent variables, called covariates, which make the model fit better. For

example, body mass is often a covariate in calculations of drug effects on organ weight. Since organ weights vary by body mass, body mass can explain some of the differences in organ weights, which makes estimation of the remaining differences more accurate. Note that body mass can be a dependent variable and a covariate in the same study, but not in the same analysis.

Interactions between independent variables may be tested by specifying the interaction in the software model or by creating another independent variable that is the multiplication of the values of the variables that are suspected to interact. Similarly, if the software does not allow easy specification of a quadratic model, such models can be tested by creating another independent variable that is the square of the variable that is needed for a quadratic fit. For both quadratic modeling and interaction effects, the original variables must still be included in the model.

For interval independent variables, ANOVA tests for a linear relationship with the dependent variable; for binary independent variables ANOVA tests if the two levels of the binary variable have equal means; and for categorical independent variables ANOVA tests if all groups have equal means. Just knowing means are unequal without knowing which means vary is not normally useful, so other tests to determine differences between levels are used to give a more detailed answer. These secondary tests are called *post hoc* tests, and to preserve the overall false positive rate, they must be used if and only if the first test finds significance. Possible *post hoc* tests for ANOVA are Duncan's (Duncan, 1955), which tests for all possible differences, and Dunnett's (Dunnett, 1955 and 1964), which tests for statistical differences between one specific group and all others and is therefore useful to test for differences from control groups. *Post hoc* tests will sometimes fail to find significance between any paired groups even when the overall test is significant and this lack of result is most common for ordinal data. This situation is not necessarily an error and occurs because results usually have more accuracy based on all the data rather than a subset.

Assumptions and limitations:

- ANOVA assumes the data are normal after adjustment for the independent variables. However, the results of ANOVA are not seriously changed by moderate departures from normality or by modest levels of other analysis limiters such as outliers or heteroscedasticity.
- ANOVA tests for a linear relationship (interval variables) or additive effects (binary or categorical variables). ANOVA can test for quadratic curves but the investigator must specify that before analysis. ANOVA will not correctly test for complex curves.

### Student's *t*-test

Student's *t*-test attempts to determine if the means of the two groups are equal.

Assumptions and limitations:

- The *t*-test assumes the data are normal and homoscedastic (equal variance for all data). The *t*-test is resistant to moderate deviations from assumptions and Cochran's *t*-test can be used for heteroscedastic groups.
- Paired samples, i.e., exactly two samples from the same animal, should use the paired *t*-test.

### Mann-Whitney U test

The Mann-Whitney U test (Mann and Whitney, 1947) is an extension of the Wilcoxon rank-sum test and is also called the Mann-Whitney-Wilcoxon (MWW) test. The MWW test attempts to determine if the two levels of the interval independent variable have equal medians.

Assumptions and limitations:

- The Mann-Whitney test should not be used on paired data. Instead use the Wilcoxon rank sum (Wilcoxon, 1945) for paired data.

### Kruskall-Wallis

The Kruskal-Wallis test (Kruskall and Wallace, 1952) is simply ANOVA on the data replaced by their ranks (1 for the smallest data point, 2 for the next smallest, etc.) and therefore is also applicable to already ranked data. The test can be viewed as testing equality of the medians.

Assumptions and limitations:

- A significant finding does not show which groups are different. To perform *post hoc* tests, examine the groups two at a time with the Mann-Whitney U test.
- Too many tied values will increase the false-positive rate.

### Logistic regression

Strictly speaking, logistic regression is used to predict the probability of an event that can only be measured by its absence (value 0) or presence (value 1), but it can be used to model other dependent binary data also. An example logistic curve is shown in Figure 12.1. The probit model (not shown) is also a reasonable test for similarly shaped responses. Logistic regression should be used instead of Fisher's exact test and chi-square tests when modeling. Common uses include estimating population response rates or toxicity rates based on drug dosage. Like ANOVA, logistic regression can be extended to handle any mixture of interval, binary and categorical

independent variables. The version of logistic regression listed here tests whether the independent variable is correlated with the dependent variable.

Assumptions and limitations (both logistic and probit models):

- The response to independent interval variables is assumed to be monotone, i.e., as the interval variable increases, the likelihood of the response either consistently increases or consistently decreases. Also, both models assume specific shapes and data that do not match those shapes will yield inaccurate or biased results.
- Both models are poor estimators when samples sizes are small.

### Exact tests and chi-square tests

Both chi-square tests and Fisher's exact test (Fisher, 1922) test for independence, i.e., the alternative hypothesis is "some relationship" without defining the relationship. Statistics courses often teach the two-by-two ( $2 \times 2$ ) case as an introduction to the larger, row-by-column ( $R \times C$ ) case but the methods for the  $R \times C$  case encompass the  $2 \times 2$  case. Pearson's chi-square is the computationally simplest and best known chi-square test. Fisher's test was originally described only for a  $2 \times 2$  table, i.e., one independent binary variable and one dependent binary variable, but statisticians have developed similar exact tests for a single categorical independent variable or a mixture of binary and categorical independent variables. However, not all statistical software packages will have exact tests beyond the  $2 \times 2$  case.

Assumptions and limitations:

- Exact tests are too conservative (alpha is not fully controllable and smaller than expected).
- Exact tests are computationally intensive for larger sample sizes.
- Chi-square tests do not show where groups are different. The *post hoc* test for the chi-square is to reduce the data to two groups and test using Fisher's exact test or the  $2 \times 2$  chi-square.
- Chi-square tests require larger data sets to be accurate. To determine whether exact tests or chi-square tests are appropriate, lay out the data in tables with the cell count being the number of observations for each unique combination of the variable values. If any cell is less than 10 in the  $2 \times 2$  case or more than 20% of cells are less than 5 in the  $R \times C$  case, then exact methods should be used, if available. There are some statistical ways around this data volume limitation but the easiest method is for an investigator is to combine categories until either Fisher's or a chi-square test is calculable.

### Cochran-Mantel-Haenszel tests

Cochran, Mantel and Haenszel collaborated on developing statistics that work well for ordinal data (Cochran, 1954; Mantel and Haenszel, 1959; Mantel, 1963), collectively abbreviated CMH statistics. The three tests of note, referred to as CMH1, CMH2 and CMH3 from SAS® terminology (SAS Institute, 2000), ask the following questions:

- CMH1, a.k.a. the Mantel-Haenszel test: Is there a linear association between the dependent and independent variable?
- CMH2: Do the mean scores of the dependent variable vary by levels of the independent variable?
- CMH3: Is there some kind of association between the dependent and independent variables?

Most software packages will have CMH1 and call it the Mantel-Haenszel test. Names and availability vary for the other two tests. Which test is used should be based on the exact question that needs to be answered (linearity, difference in means or association). When in doubt, CMH1 is more readily available and is appropriate for most analysis where the dependent variable is ordinal.

Assumptions and limitations:

- CMH2 and CMH3 do not show where groups are different. The *post hoc* test for the chi-square is to reduce the data to two groups and test using the appropriate test from Table 12.4.
- CMH statistics are approximations and should not be used for data with small cell counts under essentially the same restrictions as the  $R \times C$  chi-square test above.

### MANOVA and MANCOVA

Multivariate Analysis of Variance (MANOVA) and Multivariate Analysis of Covariance (MANCOVA) are extensions of ANOVA for more than one interval dependent variable. MANOVA should be used instead of separate ANOVAs when the investigator suspects interaction between both the independent and dependent variables.

Assumptions and limitations:

- Despite the similarity of names to ANOVA, both the generated statistics and the interpretation of MANOVA are different from ANOVA and beyond the scope of this chapter.

### Model selection

Model selection means production of a statistical model where all of the independent variables in the model have

a strong relationship to the dependent variables. This normally involves dimension reduction because it is rare that all measured independent variables actually have a known direct or strong relationship to the dependent variables. Model selection generally either removes unimportant independent variables from the model (feature selection) or transforms the independent variables to reduce variable count (feature extraction). Most feature selection methods involve three parts:

- A calculated statistic called a metric or scoring metric quantifying how strongly the independent variable(s) are related to the dependent variable(s). The exact statistic used depends on the statistical model used but commonly used statistics are F, Mallows' Cp, Akaike's Information Criterion (AIC) and Bayesian Information Criteria (BIC).
- A cutoff that is compared to the metric to determine when inclusion or exclusion of variables has improved the model. The exact cutoff depends on the statistic used.
- A procedure to decide how independent variables are introduced or eliminated from the models used in intermediate estimations. Examples include forward selection and backward elimination.

A hypothesis testing method quantifies the relationship between variables and therefore can be used in feature selection given an appropriate cutoff and variable selection procedure. However, feature extraction methods usually do not use a hypothesis testing procedure and those methods do not follow the three-part distinction above. The primary limitation of all model selection methods is that the calculated model will fit the specific data used better than it will fit the overall population that the specific data are drawn from. This limitation also implies that the independent variables chosen by model selection are not necessarily those that are important in the whole population. Therefore, in order to make a model usable to the larger population, some form of model validation must be implemented. Model validation involves using data other than the test set that the model was fit for to update the model.

One increasingly common type of model selection problem that is difficult to evaluate is called "high  $p$ , low  $N$ ," indicating the number of potential predictor variables ( $p$ ) is higher than the number of experimental units measured ( $N$ ). Examples in toxicology include attempts to correlate the prevalence or severity of a disease or condition with DNA or mRNA microarray results. Since microarrays can return tens of thousands of results for every sample, there are inevitably more independent variables (predictor variables) than samples. Three good methods of analyzing high  $p$ , low  $N$  data are Principal Component Analysis (PCA), the Least

Absolute Shrinkage and Selection Operator (LASSO or more commonly lasso) and the newer Bayesian Elastic Net. PCA was originally described by Karl Pearson in (Pearson, 1901), although not by that name. The lasso technique was originally described by Robert Tibshirani (Tibshirani, 1996) and is now a family of techniques with specific applications in many areas, including survival modeling. Bayesian Elastic Net (Zou and Hastie, 2005) is relatively new and combines features from several other older techniques. There are also a number of other equally valid techniques for handling high  $p$ , low  $N$  data. Investigators interested in learning more should explore the field of statistical regularization or more generally the fields of data mining and machine learning.

Model selection is in many ways a more complex topic than hypothesis testing, so further expansion is beyond the scope of this chapter.

## INTERPRETING AND DISPLAYING THE RESULTS

The tests listed in Table 12.4 will report some measure of statistical significance for each independent term in the model. Usually the desired answer is the  $p$ -value, which is the probability of the differences seen in the independent variable occurring by chance alone. If the probability is less than the pre-selected  $\alpha$  then the variable is considered significant and the null hypothesis of no relationship is rejected. The way the output presents the  $p$ -value will vary depending on the software and the test but terminology such as " $Pr < F$ ," " $p \leq t$ " and "significance" are some common column headers for  $p$ -values. Many of the tests will also report estimates of effects. Binary, categorical and ordinal effect estimates are reported as differences from one level of the variable's value, e.g., one group is the baseline and the other group estimates are reported as differences from baseline. Linear estimates are the slope of the best fit line. Estimates based on more complex models are best understood by graphing the model's best fit. Software does not always report confidence intervals for the effects but the investigator should request confidence intervals for at least the main variables because they allow more detailed information than a simple accept or reject decision. Confidence intervals are based on  $1 - \alpha$  so with  $\alpha = 0.05$  or 5%, the corresponding confidence interval would be  $1 - 0.05 = 0.95$  or a 95% confidence interval. Interpretation of confidence intervals is tricky – new students of statistics often read a 95% confidence interval as meaning there is a 95% chance that the real value of the effect falls in the interval. However, the real value of the effect is either 100% in the interval or not, so a statement of probability

is misleading at best. A 95% confidence interval really means that if the study were run multiple times in an identical manner then 95% of the resulting confidence intervals would contain the true value of the effect (also assuming the model is correct). For most types of results, confidence intervals that include zero indicate the independent variable has no statistically significant effect. This is true for estimates of risks and odds but for risk and odds *ratios* then confidence intervals that include one indicate no significant effect.

For the relatively simple analyses presented here, any significant effects should be discernible from the graphs or tables and, if not, may indicate a mistake in analysis. Therefore, any significant effects found should be graphed. The estimated effects from some ANOVA models may not be the same as the simple difference of group means. This happens because ANOVA adjusts for other terms in the model and also because ANOVA uses a mean estimation method called least squares mean instead of using the simple mean. The resulting estimates of mean effects can show either a more or less noticeable difference than the original raw means. As an example, examine the first panel of Figure 12.6, the one titled "Gender has No Effect." Simple means of the responses by gender would show some difference in average response. Nevertheless, the slope and intercept of the responses for males and females are essentially identical so ANOVA would report correctly that gender has no effect on response. This is because ANOVA adjusts for the difference in dose per body weight between males and females.

Generally, when interpreting statistical results the investigator should use professional judgment, avoid statements about causation and control the scope of their conclusions based on the various conditions of the test and the analysis. Variables that are highly significant in one study may show as not significant for follow-up studies, so at a minimum the investigator should ask whether significant findings make sense in a larger context and what post-analysis measures could be used to further test the effects found.

## LEARNING MORE

One rapidly expanding field of statistics that was not previously mentioned is Bayesian statistics. Bayesian statistics started with Thomas Bayes (Bayes and Price, 1763), who formalized a method of incorporating prior knowledge into a specific type of probability estimation. The ability to incorporate previous information into analyses is one of the strong points of Bayesian statistics and is important for veterinary toxicologists who

want to use findings from previous studies to improve estimations in future studies. Bayesian statistics are also well integrated into decision theory (quantifying how to make optimal decisions, including resource spending), which is important for investigators who have input into study planning.

Another rapidly expanding field of statistics applicable to toxicology is meta-analysis, which is the study of how to combine results from multiple studies to improve estimates of efficacy or safety. The basic steps are: define the question of interest; determine how the data will be obtained (literature searches are most common); set consistent criteria for which studies are included in the analysis; and select the statistical model which will be used to combine the study information. One weakness of meta-analysis is that it is sensitive to the “garbage in, garbage out” problem, i.e., even a well-executed meta-analysis that uses improperly performed studies can lead to incorrect results. Also, meta-analyses are inherently far more complex than single-study statistical methods, so subtle biases are not readily detectable. Nevertheless, the need for meta-analysis is increasing quickly because of the explosion of available data and careful meta-analyses have significant value. Toxicologists who want a reference that has both introductory and advanced meta-analysis material should consider Sutton, Abrams, Jones, Sheldon and Song’s book *Methods for Meta-Analysis in Medical Research* (Sutton *et al.*, 2000).

For most fundamental biostatistics techniques the internet is the fastest readily available resource, but is often lacking in factual reliability and address stability. Fortunately, most search engines will return formulae, examples and even online tests with searches in the general form: [name of statistical method] [desired result]. Example searches include: Mann-Whitney example, *t*-test online, Pearson’s chi-square formula and Fisher’s exact test limitations. All internet sources should be verified by finding the original reference or from multiple sites. More detail and reliability can be found in online statistical software manuals and biostatistics course notes. Online software manuals usually show up in a general search but can be found by going to the software manufacturer’s site; course notes can be found with either a general search, e.g., “statistics course notes” in a search engine, or a site-specific search of universities with statistic departments. Similarly, many textbooks and references can be searched or read online in part or in full using sites such as Google Scholar (scholar.google.com), Google Books (books.google.com) or book sellers such as Amazon (www.amazon.com). (The authors have no financial or personal interests in these companies.) Ultimately, however, college-level courses followed by practice in the techniques learned are the best way to become proficient in toxicology biostatistics.

If the investigator needs timely, in-depth expertise then the American Statistical Association (ASA) has a searchable list of consultants at <http://www.amstat.org/consultantdirectory/index.cfm> and general web searches for “statistical consulting” or a similar phrase will return a large number of possibilities. Also, university professors and occasionally graduate students perform consulting.

# Toxicology and the law

Michael J. Murphy

## INTRODUCTION

Much of the law of admissibility of scientific expert testimony arises from toxic tort cases. Consequently, the discipline of toxicology has strongly influenced the legal standards by which scientific expert testimony is admitted in a legal venue.<sup>1</sup>

This chapter uses a hypothetical example of legal issues that may arise in an animal toxicosis case to illustrate application of the law. It is intended to introduce toxicologists, and other scientists, with a broad overview of some of the legal issues that may arise when a medical case becomes a “legal case.” This chapter is not, and is not intended to be, a comprehensive review of the law. Neither is it intended to provide an outline of steps to take for a particular case in a particular jurisdiction.<sup>2</sup>

This chapter primarily relies on the Federal Rules of Evidence, and limited case law, to identify issues<sup>3</sup> that may arise when the findings of a medical diagnosis are used in the courtroom. It focuses on the admissibility of expert testimony in a legal proceeding. However, the reasons for conducting toxicology analyses, jurisdiction, standard of proof and evidence are briefly summarized

to provide a foundation for the role of the expert testimony. The chapter concludes with some questions to consider when analyzing a toxicology case.

## REASONS FOR CONDUCTING TOXICOLOGY ANALYSES

Toxicology has been defined as the scientific *study of adverse effects of chemicals on living organisms* (Eaton and Klaassen, 2001). A toxicologist is one trained to examine the nature of those effects and assess the probability of their occurrence (Eaton and Klaassen, 2001). Exposure, dose response and variability of that response are fundamental principles in the science of toxicology (Eaton and Klaassen, 2001). A showing that the toxicologist offered as an expert witness has applied these fundamental principles to the facts of the case at hand will likely be useful in the determination of whether a toxicologist’s testimony will, or will not, be admissible as evidence. The factors that the judge uses to make this determination are discussed in the expert witness section at the end of this chapter.

A toxicologist relies on analytical toxicology analyses in many toxicology cases. In most instances, it is known at the time the sample is submitted for analytical chemistry analysis that the results of that analysis will be used for legal purposes. Racing chemistry laboratories are one example in the veterinary profession where it is known from the outset that the results of the analytical chemistry testing performed will be used in a legal enforcement setting. In some instances, however, the purpose to which the results will be applied is not known, or,

<sup>1</sup>Venue. The particular county, or geographical area, in which a court with jurisdiction may hear and determine a case. *Black’s Law Dictionary*.

<sup>2</sup>Jurisdiction. It is the power of the court to decide a matter in controversy and presupposes the existence of a duly constituted court with control over the subject matter and the parties.

<sup>3</sup>Issue. A single, certain and material point, deduced by the allegations and pleadings of the parties, which is affirmed on the one side and denied on the other.

more commonly, that purpose changes after the testing is completed.

### **When the reason for testing the sample is known**

Samples are analyzed for the presence of chemical toxins for many reasons and in many settings. Analyses may take place in academic, governmental or private laboratories. Analyses performed in these laboratories may each serve a different purpose, such as research, enforcement actions, preclinical or other regulatory testing, or clinical diagnoses.

Toxicology analyses in academic settings are primarily conducted to support one's research or scholarly efforts. One example is the development of new analytical methods. Another example is the characterization of adverse effects of a particular dose of a particular chemical in a given species. Similarly, researchers may observe the clinical signs and adverse effects of animals exposed to chemicals, then compile these effects in retrospective or prospective case reports in the peer-reviewed literature. Such literature may be useful to support a general causation<sup>4</sup> argument in a legal case. However, the medical case itself, or even the analyses performed on that medical case, may not be admissible in court because of insufficient documentation supporting authenticity. Other laboratories may provide such documentation.

Veterinary diagnostic laboratories normally have some government support to assist in the clinical diagnosis of diseased animals. Such analyses are normally aimed at assisting in the determination of whether an animal may or may not have been exposed to a particular chemical, and, if so, whether the animal has or has not experienced a toxicosis as a result of that exposure. These chemical analyses may give qualitative, semi-quantitative or quantitative results.

Many contemporary analytical chemistry procedures performed in each of the above laboratory types allow detection of the presence of chemicals in biological samples that represent only "background" or "normal" exposure to that chemical. One example is many micro nutrients, such as vitamins A and E, copper, iron, magnesium, selenium and zinc. Similarly, lead may be detected at "background" concentrations in blood, liver or kidney by many analytical toxicology methods available today. Consequently, the detection of the chemical is not "diagnostic" for toxicosis from that chemical, but merely indicates exposure. Information beyond the concentration of a chemical in tissues is often required to reach a toxicosis

diagnosis. The distinction between "exposure to" and "toxicosis from" a chemical is fundamental scientifically and in a legal venue.

Samples are received from many sources. Most diagnostic laboratories accept samples from veterinarians, animal owners, animal industries and others. The circumstances of the collection and handling of the sample prior to submission in the diagnostic laboratory is rarely known with certainty. Similarly, routine protocols in a diagnostic laboratory may be different than those in an enforcement laboratory, particularly with respect to sample tracking, documentation and disposal.

Some government and some private laboratories focus on performing chemical analyses in support of legal enforcement actions. Examples of such laboratories include racing chemistry laboratories, and State or Federal Departments of Agriculture or Health. Many of these laboratories have inspectors who insure proper sample collection and transport to the laboratory. In addition, sample tracking, control, retention and disposal are generally better documented in laboratories devoted to enforcement action than those devoted to research or routine diagnostic testing. The analytical methods used in an enforcement setting have often have been validated by AOACI<sup>5</sup> or a similar entity. This validation often demonstrates that the method has been shown to be reliable in multiple laboratories for quantifying the concentration of an analyte, or a group of analytes, in a specific matrix.

The analytical methods useful in a diagnostic setting may be different from those in an enforcement or research setting. The analytical methods used to support a diagnostic case are often influenced by cost and turn-around time. On the other hand, those in an enforcement setting may be more influenced by reliability of the results reported. These factors directly and indirectly influence the collection of the original sample, tracking of the sample in the laboratory, sample retention, document retention and sample disposal protocols. Protocols appropriate for the development of a method in a research laboratory may not be appropriate for use in an enforcement setting. These factors should be taken into account and samples sent to the appropriate laboratory, when the reason for the analysis is known. The reason is not always known.

### **When the reason for testing the sample is not known or changes after testing**

Problems are more likely to occur if the purpose for which the sample is tested is not known at the times of testing, or changes after the testing is completed. These problems

<sup>4</sup>Causation. The fact of being the cause of something produced or happening. The act by which an effect is produced.

<sup>5</sup>Association of Official Analytical Chemists International.

may give rise to angst on the part of the toxicologist, counsel and others. This angst may occur if sample collection, tracking, analysis and interpretation have not been documented in a way that supports proof of reliability in a legal venue. Questions of authenticity and reliability are more likely to arise in analyses performed in a research, routine clinic or diagnostic laboratory setting than those collected and performed by enforcement personnel. Medical samples submitted and tested for one purpose may not be reliable if used for another purpose. In short, the lack of sample tracking or chain of custody documentation may seriously erode the admissibility of laboratory results. A diagnosis may not be supported without laboratory results and a legal case may not succeed without the diagnosis. Put more bluntly, insufficient sample collection, retention and chain of custody documentation can be a huge problem for a plaintiff or prosecutor in a legal venue. A hypothetical case may help illustrate the application of a number of the following legal concepts.

### Hypothetical case

A hypothetical individual employee of a feed additive manufacturer intentionally adds a foreign chemical to a feed premix during a step in the manufacturing process. The feed premix is distributed to many states. Many local mills purchase the premix and incorporate it into feed in appropriate amounts. The mill then delivers that feed to its customers – animal owners. These animal owners offer that finished feed to their animals in appropriate amounts. These animals ingest the feed, then develop adverse effects. An adverse effect in one of the animals is death. An animal that died after ingesting this feed is submitted to a local diagnostic laboratory by the animal owner. The owner of the animal has not made any association between the new feed and the death of the animal, so the feed is not delivered when the animal is, and the new feed delivery is not part of the history provided to the diagnostic laboratory. The laboratory does a routine necropsy and case workup. A feed additive is mentioned to the animal owner as one of the possible differential diagnostic causes for the lesions seen at necropsy. The owner then takes a grab sample of feed out of the total mixed ration mixer and takes it to the diagnostic laboratory. The chemical is detected in the feed at concentrations sufficiently high to cause the lesions observed in the dead animal.

Various types of legal claims<sup>6</sup> could arise from this case. The results of diagnostic testing may be offered as fact by the animal owner, feed manufacturer, state and

federal agencies, or some combination thereof, against one or more parties. An insurance claim and government enforcement action are discussed very briefly before continuing with issues that arise in civil or criminal litigation.<sup>7</sup>

The results of a routine diagnostic case may now be offered as fact in an insurance claim. The animal owner will claim that the feed provided by the distributor caused the toxicosis experienced by the owner's animals. The animal owner may file a claim with the distributor of the feed for the harm done to her animals. The distributor, or the distributor's insurance company, may settle the claim with the animal owner if all agree. If all do not agree, a civil suit may be filed. The issues that arise in the civil suit are discussed in the next section.

The dispute<sup>8</sup> between the animal owner and the feed distributor involves private parties. The case may also give rise to an enforcement action. These actions may be on the part of one or more agencies in one or more states, the federal government, or any combination of state and federal government. One or more agencies of the state in which the animal was harmed may have statutory authority to protect the health of animals, humans or both. These agencies may include the State Department of Agriculture, the State Department of Health, the State Department of Natural Resources, the State Board of Animal Health or other similar agencies. A state agency may choose to take enforcement action against the feed distributor, premix manufacturer or both in order to protect the health of animals or humans in its state.

The state agency may collect its own samples and perform its own analyses prior to taking any enforcement action. The agency may determine that the concentration of chemical in the feed is greater than a published tolerance or action level for that chemical in that feed. This agency action may end with a fine, recall or other administrative action, if both sides agree.

If both sides do not agree, the feed distributor and premix manufacturer may "appeal" the agency's decision. This appeal may go to an administrative law judge or a similar official within, or outside, the agency, depending on the administrative structure of that particular agency. If the feed manufacturer or premix manufacturer agrees with the ruling of the administrative law judge, the dispute is finished. If all do not agree, the distributor or manufacturer of the feed may choose to appeal the decision of the administrative law judge to a district civil court. This puts the dispute in a venue similar to a civil suit as discussed below.

<sup>7</sup>Litigation. A lawsuit. Legal action, including all proceedings therein. Contest in a court of law for the purpose of enforcing a right or seeking a remedy.

<sup>8</sup>Dispute. A conflict or controversy, a conflict of claims or rights, an assertion of a right, claim, of demand on one side, met by contrary claims or allegations on the other.

<sup>6</sup>Claim. A cause of action. To demand as one's own or as one's right, to assert, to urge, to insist. Means by or through which claimant obtains possession or enjoyment or privilege or thing.

Agencies are given deference at the district court level, making this an increasingly difficult, but not insurmountable, argument to win. The specialty of administrative law is devoted to the details of administrative procedure that arises in such actions. Administrative law is beyond the scope of this chapter.

Federal agencies may also have an interest in the animal case. The Federal Food and Drug Administration (FDA) may have an interest in the case because the feed additive impacted interstate commerce when it crossed state lines, and impacted the health of the public when it caused toxicosis of a food animal. The FDA has authority to protect the public health. It has authority to take administrative action against the manufacturer of the feed similar to that discussed for the state agencies above in that protection of the public's health.

Although agency decisions are normally given deference in the courtroom, regulations developed by agencies may not always address the issue of causation. Agency regulations are often promulgated to protect populations rather than individuals.<sup>9</sup> The affect on an individual referred to as specific causation is discussed in "Specific causation – the differential diagnosis," below. The distinction between enforcement actions taken by agencies to benefit the public as a whole and legally admissible specific causation in an individual animal is not always appreciated.

This distinction may be illustrated by a hypothetical example. A bulk tank load of milk is tested in the receiving bay and found to be positive for the presence of beta-lactam antibiotics using a test kit marketed and validated for this purpose. The entire load of milk is dumped and the producer whose individual sample is positive is charged for the load of milk. Paying for the tanker load of milk in this situation is a contractual agreement between the milk producer and the bulk milk buyer.

The test kit is approved and validated for use in administrative action. That action is to assist in the public policy of preventing exposure of humans to beta-lactam antibiotics to prevent allergic reactions, and to reduce the likelihood of developing strains of bacteria that are pathogenic to humans and resistant to beta-lactam antibiotics. The test kit is sufficient to support the administrative action of preventing these antibiotics from entering the human food supply.

Further analytical chemistry analysis may be required to distinguish penicillic acid from penicillin G from ticarcillin, as an extreme example. This distinction may be important because of the implication raised as to the potential source of the antibiotic in the bulk tank – feed versus a treated cow versus "spiking" the bulk tank. In short, a test that is entirely acceptable for agency action may not be acceptable for a specific type of litigation.

<sup>9</sup>See, e.g., *Troy Corp., AFL-CIO and Simpson*.

This concept is expanded upon in the section on specific causation below. See Dr. Post's chapter on regulatory veterinary medicine for a further discussion of agency issues.

The results of diagnostic testing may rarely be offered as fact in a criminal case. Animal poisoning cases have rarely risen to the level of criminal action. The addition of the chemical to the feed with the intention of causing a toxicosis may be a crime based on animal cruelty or chemical terrorism statutes. The executive branch of government may then choose to prosecute the case. The state – often through its Attorney General's office – may choose to prosecute under an animal cruelty statute. Similarly, the Department of Justice may file criminal prosecution charges if the act is considered to be one of chemical terrorism. In these instances the state or federal government is a direct party in the case.

This discussion of legal venue is not exhaustive. The purpose of this section is merely to indicate how a routine clinical or diagnostic case could become involved in a variety of legal venues including insurance claims, administrative action, civil and criminal litigation at the state and federal levels.

In summary, those samples used for the purpose known at the time of submission to a laboratory can, with some reasonable care, be handled, analyzed, interpreted and stored in a manner consistent with that purpose. Angst may arise on the part of the animal owner, veterinarian, laboratory personnel, counsel and others, in those instances where the application of results of testing are used in a venue not anticipated at the time of sample submission, particularly in those laboratories not accustomed to litigation work. This angst may rise when the documentation of laboratory results is found to not be sufficiently authentic or reliable to support a legal case. The importance of authenticity and reliability are discussed in the evidence section below, immediately after a brief discussion of jurisdiction and standard of "proof."

## JURISDICTION – WHAT ARE THE RULES IN THIS FIGHT AND WHO DECIDES THE WINNER?

The parties have met, discussed and agreed to disagree on reaching a settlement<sup>10</sup> on the insurance claim. They decide to take the case "to court." The owner of the

<sup>10</sup>Settlement. Payment or satisfaction. In legal parlance, implies meeting of the minds or parties to transaction or controversy, an adjustment of differences or accounts, a coming to an agreement.

animals will normally be the plaintiff<sup>11</sup> and the distributor of the feed will normally be the defendant<sup>12</sup> in this legal case. The manufacturer of the premix is also likely to be named as a defendant. The animal owner may be a natural person or may have formed a legal entity<sup>13</sup> like a family farm corporation. The feed manufacturer and premix manufacturer may be businesses organized as sole proprietorships, partnerships, corporations or other legal entities.

A question arises as to “which court” will decide the dispute. The state and federal governments already have authority to rule on disputes between their citizens. This authority ultimately arises from the respective constitutions. State constitutions most commonly delegate authority to the state judicial system to enforce the laws passed by the state legislature. Many state judicial systems have a three tiered structure composed of district courts, courts of appeals and a supreme court, each with increasing authority. Similarly, the federal constitution authorizes the federal judicial system which has district courts, courts of appeals and the U.S. Supreme Court.

Most civil suits that are filed in the United States do not actually go to trial. A settlement is reached in the vast majority of civil cases. This settlement may be reached by the parties on their own, after mediation or arbitration, or even after litigation has begun, but before a judgment is entered.

Mediation and arbitration are two forms of “alternative dispute resolution” (ADR). An outcome reached after ADR may or may not be disputed later in court depending on the final agreement of the parties in the ADR process. Judges often encourage ADR even when civil litigation is filed. Authority may be given by contract. Disputing parties may have agreed not to litigate at all but rather to use ADR. ADR is increasingly used to settle disputes between companies because it can be faster and cheaper than litigation, and because both parties have more control over the outcome of the dispute. Two parties who agree to submit themselves to ADR must grant authority to the mediator or arbitrator at the outset of the deliberation by way of contract. This authority prevails for as long as the contract between the parties is in force. Authority already exists for government.

Parties with an ongoing relationship may have made a contractual agreement to argue any disputes that arise under that contract according to the laws of a particular

state. For example, the manufacturer of the feed additive and the manufacturer of the final feed may have agreed to argue any dispute they may have under that contract according to the laws of Minnesota. One reason for this may be that both parties agree that the cost of arguing jurisdiction for a distributor with outlets in many states, and a manufacturer with plants in many states, is not in the economic best interest of either company.

The parties will need to decide on the state in which the dispute – lawsuit – will be litigated if they have not already made this decision by prior contract. Individuals, and particularly companies, may be citizens of more than one jurisdiction, consequently parties may need to decide which judicial system they choose to “sue out” the case in. This decision may influence the outcome of the dispute because of differences in laws on a particular issue between states. Similarly, federal law on a particular point may be different than that of state law on the same point, so one party may prefer to argue in a federal court and the other in a state court. The choice of venue may then become a significant part of the dispute that must be decided before the merits of the case can be argued. This jurisdictional decision will normally be made by the judge in the venue where the case was originally filed.

Each state has rules governing the procedures to be followed in conducting a civil trial, and procedures to be followed in conducting a criminal trial. Although these procedural rules may have many similarities between states, they are not uniform across all states. The federal rules are more consistent nationwide.

The federal judicial system also has rules governing civil procedure and those governing criminal procedure. These rules are the same across states, although they may be interpreted differently in different federal judicial districts. In short, administrative rules guide administrative actions, state rules guide state civil or state criminal actions and federal rules guide federal civil and criminal actions.

In our hypothetical example, the manufacturer of the premix and the manufacturer of the feed may have agreed to argue any disputes that arise under their business contract according to the laws of Minnesota. The animal owner who chooses to sue the manufacturer of the feed may choose to sue in state court in the state in which the owner fed the feed to their animal, or perhaps in the federal court representing the same geographic area. One argument that may be used to argue that the case belongs in the federal court system is that the feed crossed state lines and therefore impacted interstate commerce. Other elements that may be required to establish federal jurisdiction are beyond the scope of this chapter.

A judgment will be entered by the judge if the dispute goes all the way through trial. Thus the animal owner may receive compensation at the insurance claim,

<sup>11</sup> Plaintiff. A person who brings an action; the party who complains or sues in a civil action and is so named on the record. A person who seeks remedial relief.

<sup>12</sup> Defendant. The person defending or denying; the party against whom relief or recovery is sought in an action or suit to the accused in a criminal case.

<sup>13</sup> Entity. A real being. An organization or being that possesses separate existence for tax purposes.

settlement or judgment level of this dispute if the animal owner prevails.

The point of this section is primarily to indicate that the procedures by which the dispute is handled may be different between states for an insurance claim, arbitration, mediation or litigation. These distinctions between state court systems are beyond the scope of this chapter. On the other hand, the federal judicial system has procedures that are generally applied across the country. They are more similar nationwide, so they are described below to indicate some procedural issues that may arise in toxicology cases. Although many disputes involving animal toxicoses are not tried in federal courts, the federal procedural rules provided below illustrate issues that are likely to be similar across the country.

## STANDARD OF PROOF – HOW SURE DO I NEED TO BE?

One party needs to persuade the other party once a dispute develops. This need is normally referred to as the burden of persuasion in a legal setting.<sup>14,15,16</sup> The burden

### <sup>14</sup>ARTICLE III. PRESUMPTIONS IN CIVIL ACTIONS AND PROCEEDINGS

Rule 301. Presumptions in General in Civil Actions and Proceedings

In all civil actions and proceedings not otherwise provided for by Act of Congress or by these rules, a presumption imposes on the party against whom it is directed the burden of going forward with evidence to rebut or meet the presumption, but does not shift to such party the burden of proof in the sense of the risk of nonpersuasion, which remains throughout the trial upon the party on whom it was originally cast.

<sup>15</sup>Rule 302. Applicability of State Law in Civil Actions and Proceedings

In civil actions and proceedings, the effect of a presumption respecting a fact which is an element of a claim or defense as to which state law supplies the rule of decision is determined in accordance with state law.

<sup>16</sup>Rule 1101. Applicability of Rules

(a) Courts and judges. – These rules apply to the United States district courts, the District Court of Guam, the District Court of the Virgin Islands, the District Court for the Northern Mariana Islands, the United States courts of appeals, the United States Claims Court, and to United States bankruptcy judges and United States magistrate judges, in the actions, cases and proceedings and to the extent hereinafter set forth. The terms “judge” and “court” in these rules include United States bankruptcy judges and United States magistrate judges.

(b) Proceedings generally. – These rules apply generally to civil actions and proceedings, including admiralty and maritime cases, to criminal cases and proceedings, to contempt proceedings except those in which the court may act summarily, and to proceedings and cases under title 11, United States Code.

of persuasion is colloquially referred to as a “burden of proof” – a phrase that toxicologists may find familiar. This burden of persuasion is different in civil cases than it is in criminal cases. Both legal burdens may be different than that of a routine medical diagnosis. The level of medical certainty needed to treat is often presented by quoting the Hippocratic Oath: “first do no harm.” The degree of medical certainty required to treat a disease may only be that needed to give appropriate general and supportive treatment, but not that which would be required to reach an etiological diagnosis. Reaching an etiological diagnosis to any degree of medical certainty is not always done in clinical practice. Similarly, routine cases in a diagnostic laboratory may not reach an etiological diagnosis to any degree of medical certainty either. In many instances reaching an etiological diagnosis is limited by time, cost and the needs of the animal owner and veterinarian. This need may be merely to have guidance for providing supportive treatment. Other limits on the ability to provide an etiological diagnosis may be the available samples, the condition of the samples, the willingness of the owner to spend the money required to reach such a diagnosis and other factors.

This distinction between a medical diagnosis and a “legal” diagnosis is appreciated by the court system. This distinction is summarized in *Wynacht*:

There is a fundamental distinction between Dr. Z...’s ability to render a medical diagnosis based on clinical experience and her ability to render an opinion on causation of W...’s injuries. Beckman apparently does not dispute, and the Court does not question, that Dr. Z is an experienced physician, qualified to diagnose medical conditions and treat patients. The ability to diagnose medical conditions is not remotely the same, however, as the ability to deduce, delineate, and describe, in a scientifically reliable manner, the causes of these medical conditions. *Wynacht v. Beckman Instruments, Inc.* 113 F. Supp. 2d 1205, 1209 (E.D. Tenn. 2000).

In short, the diagnosis reached in a routine medical clinic is not always sufficient to meet a legal burden of persuasion. Similarly, the diagnosis reached in a routine veterinary clinic may not meet this burden either.

The legal burden of persuasion is different in civil and criminal cases. The burden in civil cases is usually either a preponderance of the evidence or clear and convincing evidence. A preponderance of the evidence is also referred to as a “more likely than not” standard. Juries are sometimes instructed that this is a 51% persuasion standard. In a civil case, the plaintiff has the burden of persuading the finder of fact – judge or jury – that his or her claim is valid with a preponderance of the evidence. Similarly, the defense has the burden of persuading the

finder of fact that their defense is valid with a preponderance of the evidence.

The burden of persuasion in criminal cases is much higher. Here, the burden of persuasion is “beyond a reasonable doubt.” The prosecutor has the burden of persuading the fact finder – judge or jury – beyond a reasonable doubt that the crime was committed by the defendant. Conversely, the defendant raises “reasonable doubt” that the prosecution has met this burden. The merits of both civil and criminal cases are argued based on evidence. Some evidence will require interpretation. Interpretation of facts is the role of the expert. The role and types of evidence follow.

## EVIDENCE

Legal cases are decided based on an application of the law to the facts of a particular case. A dispute about facts themselves or interpretation of those facts arises in many legal cases. Disputes of fact are decided by the trier of fact. The trier of fact is the judge in a bench trial. The trier of fact is the jury in a jury trial. The trier of fact learns of these facts largely through evidence.

All facts are not admissible as evidence. The judge must determine which facts are admissible as evidence and which are not as a preliminary matter. Specifically, the judge must determine “the qualifications of a person to be a witness” and “the admissibility of evidence” (Rule 104(a)). The weight and credibility of the evidence is not determined at this preliminary stage. Rather “evidence relevant to weight or credibility” is normally “introduce[d] before the jury” (Rule 104(e)).

The major factor used to determine the admissibility of evidence is relevance. “Relevant evidence” and “material fact” are two phrases that are often used synonymously. “Relevant evidence” is “evidence having any tendency to make the existence of any fact that is of consequence to the determination of the action more probable or less probable than it would be without the evidence” (Rule 401). “[A]ll relevant evidence is admissible” with few exceptions (Rule 401). “Evidence which is not relevant is not admissible” (Rule 402). For example, testimony that the sky is blue may not be admitted as relevant, because the color of the sky has no tendency to indicate that the feed did or did not cause the toxicosis in the animals.

The judge decides which facts are admissible as evidence and which are not. The factors that influence the judge’s decision on admissibility vary with the type of fact. Documents, specimens and testimony are three sources of fact that a party may desire to enter into evidence in toxicology cases.

## Documents

Documents require authentication before they can be considered as evidence. Document authentication is of increasing interest in many laboratories revisiting record retention procedures. Authentication of documents is covered by Rule 901 of the Federal Rules of Evidence.<sup>17</sup> Subsections of this rule specify the procedure for authenticating public<sup>18</sup> or ancient<sup>19</sup> documents. A laboratory will likely have additional influence on its record-keeping. For example, veterinary diagnostic laboratories are adopting ISO standards, contract research laboratories adhere to Good Laboratory Practice standards,<sup>20</sup> many state agencies have state-specific data practices requirements. While the specific requirements may vary, the general purpose is to authenticate the accuracy of the final report.

The case report and the documents supporting that case report may be required to authenticate that report in a legal proceeding. Authentication of case documents is one reason that many laboratories have established record retention procedures. A document and its underlying support are retained for 7 years in some diagnostic laboratories. The specimens themselves are also important in these proceedings.

## Specimens

Specimens are often relevant in toxicology cases. Toxicologists are well aware of the importance of accurate sample identification to establish the relevance of the results of testing a particular sample. Laboratories involved in racing chemistry, regulatory enforcement and GLP studies often have significant sample tracking documents to establish that the result of a test can be tracked to the original specimen. These sample tracking or chain of custody documents are often needed to establish that the sample tested does, in fact, relate to the case report. The absence of sample tracking or such

<sup>17</sup> Rule 901. “The requirement of authentication or identification as a condition precedent to admissibility is satisfied by evidence sufficient to support a finding that the matter in question is what its proponent claims.”

<sup>18</sup> Rule 90(7). “Evidence that a writing authorized by law to be recorded or filed and in fact recorded or filed in a public office, or a purported public record, report, statement, or data compilation, in any form, is from the public office where items of this nature are kept.”

<sup>19</sup> Rule 901(8). “Evidence that a document or data compilation, in any form, (A) is in such condition as to create no suspicion concerning its authenticity, (B) was in a place where it, if authentic, would likely be, and (C) has been in existence 20 years or more at the time it is offered.”

<sup>20</sup> 21 CFR 58.

chain of custody data may eviscerate a legal claim. The federal judicial system is aware of this as well. It considers as relevant evidence "Comparison by the trier of fact or by expert witnesses with specimens which have been authenticated" (Rule 901(3)). Split sample testing in racing chemistry is an example of comparison by an expert witness with authenticated samples. Such split sample testing may be desirable in toxicology cases that reach an insurance claim, civil or criminal case level.

Toxicologists are aware of the potential for different results when different analytical methods are used. This awareness has given rise over the years to recognition of the need to "validate" tests and test results. The federal judicial system is also aware of this need. It requires "[e]vidence describing a process or system used to produce a result and showing that the process or system produces an accurate result" (Rule 901(9)). AOACI is an example of an entity that validates an analytical method for a particular matrix. The plaintiff has the burden of persuading the judge that the analytical results go with the correct sample, and the results of that sample's testing are on the correct report. Authenticating sample results for such proceedings is one reason for standard operating procedures, quality assurance samples, method validation, split sample testing and other such procedures.

Analytical toxicologists know the limits of interpretation of the results of a given test. However, some who see these reports may not be aware of these limits, so toxicologists need to take care in the wording of interpretive comments made.

## Testimony

Testimony is a third means of introducing evidence. Testimony is often gathered during the discovery portion of a legal case by taking the deposition of witnesses. Testimony may also be given orally at trial. Witnesses are under oath both at the deposition and at trial. Testimony given in a deposition may be entered into evidence at trial. This is sometimes done because the witness is not available for the trial date. Testimony may be given in a deposition, and again at trial by the same person on the same subject.

Testimony is given by both "lay" witnesses and expert witnesses. Admission of testimony from a lay witness is evaluated differently than that of an expert witness. A lay witness must have personal knowledge of the facts to which she or he is testifying. Specifically, "[a] witness may not testify to a matter unless evidence is introduced sufficient to support a finding that the witness has personal knowledge of the matter. Evidence to prove personal knowledge may, but need not, consist of the witness' own testimony..." (Rule 602).

This personal knowledge is their recollection of the event. For example, the animal owner in our hypothetical

example may testify that she did purchase the feed, that she fed it to her animals, that she observed certain clinical signs in her animals, and that she delivered a dead animal to the veterinary diagnostic laboratory.

The animal owner may be cross-examined to help verify details of the events. The animal owner's recollection may be refreshed by referring to a written document pursuant to Rule 612.<sup>21</sup>

Examples of a writing to which the animal owner may refer are a receipt and a case report from the diagnostic facility or veterinary clinic. The receipt could be used to refresh the memory of the animal owner as to precisely when and where the feed was purchased. The case report could be used to refresh the memory of the animal owner as to when the animal died, when the diagnostic testing was performed and the results of the testing. An expert witness may be required, however, to interpret the laboratory report.

## ADMISSIBILITY OF EXPERT TESTIMONY

The lay witness is not the only source of testimony. Lay testimony is a source of facts. Some of these facts must be interpreted, which is the role of the expert. Expert testimony is the other main form of introducing testimonial evidence. Expert testimony is commonly used at trial and has become the topic of a number of evidentiary rules. Federal Rules of Evidence 701 through 706 follow in their entirety.<sup>22,23,24,25,26,27</sup>

Expert testimony must not only be relevant as with a lay witness, but it must also be *reliable*. Discussion of this reliability factor constitutes most of the remainder of this

<sup>21</sup> Except as otherwise provided in criminal proceedings by section 3500 of title 18, United States Code, if a witness uses a writing to refresh memory for the purpose of testifying, either –  
(1) while testifying, or

(2) before testifying, if the court in its discretion determines it is necessary in the interests of justice, an adverse party is entitled to have the writing produced at the hearing, to inspect it, to cross-examine the witness thereon, and to introduce in evidence those portions which relate to the testimony of the witness. ...If a writing is not produced or delivered pursuant to order under this rule, the court shall make any order justice requires, except that in criminal cases when the prosecution elects not to comply, the order shall be one striking the testimony or, if the court in its discretion determines that the interests of justice so require, declaring a mistrial. Rule 612. As amended Mar. 2, 1987, eff. Oct. 1, 1987.

<sup>22</sup> Rule 701. Opinion Testimony by Lay Witnesses

If the witness is not testifying as an expert, the witness' testimony in the form of opinions or inferences is limited to those opinions or inferences which are (a) rationally based on the perception of the witness, and (b) helpful to a clear understanding

chapter. In virtually all legal cases, the judge makes preliminary rulings that determine whether the expert may testify at all, and, if so, upon which opinions. Reliability is the primary factor in the judge's determination of admissibility of expert testimony. Two approaches to determine the reliability of expert testimony have evolved, namely the "*Frye* test" and the "*Daubert* test."

## Frye

The *Frye* test is the original standard of reliability for expert testimony, and it remains in several state court systems, including Minnesota. See Table 13.1. The *Frye* test is often summarized as the "general acceptance" standard. A brief history of *Frye* may illustrate its use in a legal setting.

In 1923, a defendant was convicted of second degree murder (*Frye v. United States*). The defendant appealed the trial court's ruling because the court<sup>228</sup> did not allow the defendant to offer expert testimony. The expert testimony would have used a precursor to the "lie detector test" known as the "systolic blood pressure deception test" ("SBPD test"). The defendant's expert claimed that the SBPD test could prove whether or not a person being examined by the SBPD was attempting to deceive the examiner or conceal his guilt with regard to the crime. The judge did not allow this testimony, and the defendant was convicted. The ruling was appealed. The court of appeals held that when "admitting expert testimony deduced from a well-recognized scientific principle or discovery, the thing from which the deduction is made must be sufficiently established to have gained general acceptance in the particular field in which it belongs" (*Frye v.*

of the witness' testimony or the determination of a fact in issue, and (c) not based on scientific, technical, or other specialized knowledge within the scope of Rule 702.(As amended Mar. 2, 1987, eff. Oct. 1, 1987; Apr. 17, 2000, eff. Dec. 1, 2000.)

<sup>23</sup> Rule 702. Testimony by Experts

If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case.

Rule 702. (As amended Apr. 17, 2000, eff. Dec. 1, 2000.)

<sup>24</sup> Rule 703. Bases of Opinion Testimony by Experts

The facts or data in the particular case upon which an expert bases an opinion or inference may be those perceived by or made known to the expert at or before the hearing. If of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject, the facts or data need not be admissible in evidence in order for the opinion or inference to be admitted. Facts or data that are otherwise inadmissible shall not be disclosed to the jury by the proponent of the opinion or inference unless the court determines that their probative value in assisting the jury to evaluate the expert's opinion substantially outweighs their prejudicial effect. Rule 703. (As amended Mar. 2, 1987, eff. Oct. 1, 1987; Apr. 17, 2000, eff. Dec. 1, 2000.)

<sup>25</sup> Rule 704. Opinion on Ultimate Issue

(a) Except as provided in subdivision (b), testimony in the form of an opinion or inference otherwise admissible is not objectionable because it embraces an ultimate issue to be decided by the trier of fact.

(b) No expert witness testifying with respect to the mental state or condition of a defendant in a criminal case may state an opinion or inference as to whether the defendant did or did not have the mental state or condition constituting an element of the crime charged or of a defense thereto. Such ultimate issues are matters for the trier of fact alone. (As amended Oct. 12, 1984.)

<sup>26</sup> Rule 705. Disclosure of Facts or Data Underlying Expert Opinion

The expert may testify in terms of opinion or inference and give reasons therefore without first testifying to the underlying facts or data, unless the court requires otherwise. The expert may in any event be required to disclose the underlying facts or data on cross-examination.

(As amended Mar. 2, 1987, eff. Oct. 1, 1987; Apr. 22, 1993, eff. Dec. 1, 1993.)

<sup>27</sup> Rule 706. Court Appointed Experts

(a) Appointment. – The court may on its own motion or on the motion of any party enter an order to show cause why expert witnesses should not be appointed, and may request the parties to submit nominations. The court may appoint any expert witnesses agreed upon by the parties, and may appoint expert witnesses of its own selection. An expert witness shall not be appointed by the court unless the witness consents to act. A witness so appointed shall be informed of the witness' duties by the court in writing, a copy of which shall be filed with the clerk, or at a conference in which the parties shall have opportunity to participate. A witness so appointed shall advise the parties of the witness' findings, if any; the witness' deposition may be taken by any party; and the witness may be called to testify by the court or any party. The witness shall be subject to cross-examination by each party, including a party calling the witness.

(b) Compensation. – Expert witnesses so appointed are entitled to reasonable compensation in whatever sum the court may allow. The compensation thus fixed is payable from funds which may be provided by law in criminal cases and civil actions and proceedings involving just compensation under the Fifth Amendment. In other civil actions and proceedings the compensation shall be paid by the parties in such proportion and at such time as the court directs, and thereafter charged in like manner as other costs.

(c) Disclosure of appointment. – In the exercise of its discretion, the court may authorize disclosure to the jury of the fact that the court appointed the expert witness.

(d) Parties' experts of own selection. – Nothing in this rule limits the parties in calling expert witnesses of their own selection.

(As amended Mar. 2, 1987, eff. Oct. 1, 1987.)

<sup>28</sup> The judge is referred to as "the court" in legal writing.

TABLE 13.1 The status of *Daubert* in state courts as of 2006<sup>1</sup>

Rejecting <i>Daubert</i>	Adopting or deeming <i>Daubert</i> consistent	Neither rejecting nor adopting
Arizona	Alaska	Alabama
California	Arkansas	Hawaii
Colorado	Connecticut	Illinois

<sup>1</sup>The Status of *Daubert* in State Courts, Martin S. Kaufman, Atlantic Legal Foundation, current to March 31, 2006.

*United States* at 1013). This holding is commonly abbreviated as the “general acceptance” test. The trial court decision was upheld, because the defendant had insufficient proof that the SBPD test had gained “general acceptance.” Consequently, the defendant’s expert was not allowed to testify, so this expert testimony was not entered into evidence, and this evidence was then not available to support an argument to overturn the defendant’s conviction.

*Frye* was a federal criminal case, but the holding was later adopted in federal civil cases. Over time, *Frye* was adopted by most state courts for both civil and criminal proceedings. Minnesota reaffirmed its use of *Frye* in *Goeb v. Tharaldson*. Minnesota Supreme Court cases on the subject are briefly summarized to illustrate differences with the *Daubert* test below.

Minnesota adopted *Frye* in 1952 in the case of *State v. Kolander*. In 1980, Minnesota added an analysis to decide that testimony developed through hypnosis was inadmissible (*State v. Mack* at 768–769). Consequently, the Minnesota test for admissibility of novel scientific evidence has evolved into a two-prong *Frye-Mack* standard. The *Frye* prong first requires that a novel scientific

technique be generally accepted in the relevant scientific community, then the *Mack* prong requires that the particular evidence derived from that test have a foundation that is scientifically reliable (*Goeb* at 814; see also *State v. Anderson*, *State v. Jobe*, *State v. Moore*).

The Minnesota Supreme Court reconsidered the *Frye-Mack* two-prong test after *Daubert* passed the United States Supreme Court.<sup>29</sup> It rejected *Daubert* and sustained *Frye-Mack*, stating:

Having reviewed the cases and the commentary surrounding this issue, we reaffirm our adherence to the *Frye-Mack* standard and reject *Daubert*. Therefore, when novel scientific evidence is offered, the district court must determine whether it is generally accepted in the relevant scientific community. See *Moore*, 458 N.W.2d at 97–98; *Schwartz*, 447 N.W.2d at 424–26. In addition, the particular scientific evidence in each case must be shown to have foundational reliability. See *Moore*, 458 N.W.2d at 98; *Schwartz*, 447 N.W.2d at 426–28. Foundational reliability “requires the ‘proponent of a \* \* \* test [to] establish that the test itself is reliable and that its administration in the particular instance conformed to the procedure necessary to ensure reliability’.” *Moore*, 458 N.W.2d at 98 (alteration in original) (quoting *State v. Dille*, 258 N.W.2d 565, 567 (Minn. 1977).) Finally, as with all testimony by experts, the evidence must satisfy the requirements of Minn. R. Evid. 402 and 702 – be relevant, be given by a witness qualified as an expert, and be helpful to the trier of fact. See *State v. Nystrom*, 596 N.W.2d 256, 259 (Minn. 1999).

The Minnesota Supreme Court has held that “the *Frye-Mack* standard for admission ‘facilitates more objective and uniform rulings’” and reduces the “undesired element of subjectivity \* \* \* [in] evidentiary rulings” (*Schwartz* at 424) that may occur with *Daubert*. The Minnesota approach requires that an appellate court review a novel scientific or non-scientific technique for reliability before an expert may offer it (*State of Minnesota v. DeShay*) including DNA testing by PCR-STR (*State of Minnesota v. Nose*). With very rare exceptions,

<sup>29</sup> There have been no developments in Minnesota since *Mack* and *Schwartz* to convince us that the *Frye-Mack* standard is now incompatible with those same rules of evidence in existence at the time of these decisions. Cf. *Leahy*, 882 P.2d at 328 (reasoning that by applying the *Frye* standard after the adoption of the evidence code, the California Supreme Court had concluded *Frye* was compatible with the code); *State v. Copeland*, 922 P.2d 1304, 1314 (Wash. 1996) (noting that by adopting the rules of evidence and continuing to adhere to *Frye*, the Washington Supreme Court “signaled that *Frye* and the evidence rules coexist as the law of th[e] state [of Washington]”).

a layperson may not testify in the form of opinions or inferences (*Ray v. Miller Meester*).

However, *Frye* is no longer the standard in federal cases. The *Frye* test was superseded in federal courts by the enactment of the Federal Rules of Evidence (*Daubert* at 589). The *Frye* test has also been replaced by the *Daubert* test in many state court systems. See Table 13.1. The remainder of this section is devoted to *Daubert* since it has been adopted by the federal courts and many state court systems to determine whether expert testimony is, or is not, admitted into evidence today.

## Daubert

*Daubert* is one of three United States Supreme Court cases addressing the issue of admissibility of expert testimony. In addition, the federal court system has published a Reference Manual on Scientific Evidence to assist judges in applying these rulings. This Reference Manual contains a section devoted to toxicology and a separate section devoted to medical testimony. Much of the material below is summarized from these sources.

Three cases with rulings on the admissibility of expert testimony have reached the United States Supreme Court in recent years. The cases are *Daubert v. Merrell Dow Pharmaceuticals, Inc.* 509 U.S. 579 (1993), *General Electric Co. v. Joiner*, 522 U.S. 136 (1997), and *Kumho Tire Co. v. Carmichael*, 119 S. Ct. 1167 (1999). Both *Daubert* and *General Electric* were toxic tort cases. *General Electric* and *Kumho* are discussed first.

The holdings in *General Electric* and *Kumho* are of legal review and admission of testimony from non-scientists as experts, so they are summarized briefly. The holding in *General Electric* is primarily of legal interest. In *General Electric*, the Supreme Court held that the correct standard for an appellate court to apply in reviewing a district court's evidentiary ruling is an "abuse of discretion" standard. This holding most commonly has the effect of strengthening the decision made by the district court whether it is to admit or to not admit the expert testimony. Of interest to toxicologists and other scientists is the urging by Justice Breyer in *General Electric* that judges avail themselves of court appointed experts (*General Electric* at ???). *Kumho Tire* is not directly on point for toxicologists either.

The Supreme Court held in *Kumho Tire* that the phrases "technical" and "other specialized" knowledge in the Federal Rule of Evidence 702 allow testimony from those with "skill"- or "experience"-based expertise and not just "science"-based expertise. The Supreme Court held that an expert in tire failure analysis could testify as an expert even though his expertise was "skill" or "experience" based, rather than "science" based (*Kumho* at 1171). The *Frye-Mack* test in Minnesota offers

very few exceptions to the rule that lay witnesses may not give expert testimony. The holdings in *Daubert* are of most direct interest to toxicologists and other scientists.

Expert testimony is different from lay testimony. One difference is the possibility that "junk science" may be used to confuse, rather than assist, the trier of fact. Consequently an additional test of admissibility is applied to expert testimony. Such testimony must not only be relevant, but it must also be *reliable*. This concept is explained in the *Daubert* case. Justice Breyer "believe[s] there is an increasingly important need for law to reflect sound science" (Justice Breyer, in the Reference Manual on Scientific Evidence, p. 5). Justice Breyer also writes in the Manual on Scientific Evidence:

The judge is the evidentiary gatekeeper (*General Electric Co v Joiner*, 522 U.S. 136 (1997); *Daubert v Merrell Dow Pharms Inc*, 509 U.S. 579 (1993))). The judge, without interfering with the jury's role as trier of fact, must determine whether purported scientific evidence is "reliable" and will "assist the trier of fact" thereby keeping from juries testimony that, in Pauli's sense, isn't even good enough to be wrong. (Justice Breyer, in Manual on Scientific Evidence, p. 6)

The purpose of *Daubert's* gatekeeping requirement "is to make certain that an expert whether basing testimony upon professional studies or personal experience, employs in the courtroom the same level of intellectual rigor that characterizes the practice of an expert in the relevant field." (*Kumho Tire Co. v. Carmichael*, 119 S. Ct. 1167 (1999) at 1176. See also *Rosen v. Ciba-Geigy Corp*, 78 F.3d 316 (7th Cir) cert denied, 519 U.S. 819 (1996) at 318)

Clearly, the United States Supreme Court in *Daubert* assigned the trial judge a "gatekeeping" responsibility. This responsibility is to make a "preliminary assessment of whether the reasoning or methodology underlying the testimony is scientifically valid and whether that reasoning or methodology properly can be applied to the facts in issue" (*Daubert* at 589). The "gatekeeper" function requires district court judges to screen proffered expert testimony (*Daubert* at 589). This screening is intended to ensure that expert testimony "is not only relevant, but reliable" (*Daubert* at 589). To be relevant, the testimony "requires a valid scientific connection to the pertinent inquiry as a precondition to admissibility" (*Daubert* at 591-592). Much has been written about the reliability portion of this screening.

To meet the reliability standard, the judge must determine whether testimony is "grounded in the methods and procedures of science" (*Daubert* at 590). Consequently, an expert must account for "how and why" he or she reached the expert opinion (*Kumho* at note 27). The judge's determination is "flexible" (*Daubert*

at 594) so the trial judge has broad latitude to determine *how* to test an expert's reliability (*Kumho* at 1176), and this determination may be different in a criminal case than in a civil one (*Kumho* at 1176). Nevertheless, guidelines for determining the reliability of expert testimony exist.

Four factors were presented in *Daubert* to assist the judge in determining whether a theory or technique has been derived by the scientific method (*Daubert* at 593–594). These four factors are used to determine the theory's testability (*Carmichael* at 1522), because "[w]hether [a theory or technique] can be (and has been) tested" is the "methodology [that] distinguishes science from other fields of human inquiry" (*Daubert* at 593). In short, the four factors are testability, peer review or publication, the existence of known or potential error rates and standards controlling the techniques' operation (*Daubert* at 593).

In summary, the trial judge decides whether or not expert testimony is allowed. The means by which the judge makes this decision is flexible, but the judge often tests both the credentials of the expert and the opinion that expert offers. The expert's opinion must meet "the same standard of intellectual rigor" inside the court room as outside of it (*Kumho* at 1176). This showing of intellectual rigor requires that the expert demonstrate both "how and why" the opinion was reached. This may be done by satisfying four factors, namely (1) whether the theory or technique can be tested, (2) whether it is published or peer reviewed, (3) whether it has known or potential error rates and (4) what the control standards are.

These factors may be applied to both the analytical and interpretive portions of a toxicology case. Both *Daubert* and *General Electric* were toxic tort cases. This may be one reason that a chapter devoted to toxicology appears in the Reference Manual for Scientific Evidence. This Manual offers some questions to be asked of purported toxicology experts.

Three questions may be asked in the evaluation of a toxicology expert to determine whether the expert's testimony is reliable – and therefore admissible. These questions may be reduced to (1) is the expert qualified?, (2) has general causation been established?, and (3) has specific causation been established?

### *Is the Expert Qualified?*

The individual wanting to be allowed to testify as an expert must be "qualified as an expert by knowledge, skill, experience, training, or education, ..." (Rule 702). Toxicologists are often argued to be experts based on education, board certification and other means. Although "...no single academic degree, research specialty, or career path qualifies an individual as an expert in toxicology. ...A number of indicia of expertise can be explored, ..." (Reference Guide on Toxicology, p. 415, old).

The basis of a toxicologist's opinion is often a thorough review of the scientific literature and treatises

disclosing the adverse effects of exposure to a particular chemical (Reference Guide on toxicology, p. 415, new).

### *Has the Person Been Trained and Educated in the Discipline of Toxicology?*

An advanced degree in toxicology presumptively supports the argument that the person has been trained and educated in the discipline of toxicology. One may go to the credentialing and other means portions of the analysis if the person possesses an advanced degree in toxicology. Not all toxicologists possess such a degree, however.

Many well-qualified toxicologists do not have an advanced degree in toxicology, but do have an advanced degree in related disciplines such as pharmacology, biochemistry, environmental health, industrial hygiene or other similar fields (Reference Guide on Toxicology, p. 415). However, not all individuals in possession of these related degrees are toxicologists, so further evidence of training and education is often required of those who do not have an advanced degree in toxicology but do have an advanced degree in a related discipline.

This training and education is often in the form of college level course work or continuing education programs. The number of required courses in toxicology cannot be stated, but one such course is not enough. Specifically, "a single course in toxicology is unlikely to provide sufficient background for developing expertise in the field" (Reference Guide on Toxicology, p. 415). "A physician without particular training or experience in toxicology is unlikely to have sufficient background to evaluate the strengths and weaknesses of toxicological research" (see *Mary Sue Henifin*). "[M]ost physicians have little training in chemical toxicology and lack an understanding of exposure assessment and dose-response relationships" (see *Mary Sue Henifin*). The same is true for veterinarians and many other health care professionals. So, while the number of college courses, continuing education or other training programs required to support an argument that one is a toxicologist is not established, one such course is most likely too few. Consequently, an MD or DVM without an advanced degree in toxicology may well be found to not be a toxicologist based on training and education if they have only a course in professional school to support the claim. Certification is another way to support the argument that one is a toxicologist.

### *Has the Person Been Certified as a Toxicologist?*

Some professions have a subspecialty in toxicology with a board certification. Physicians may be certified by the American Board of Medical Toxicology.<sup>30</sup> Veterinarians

<sup>30</sup>A list of approved medical subspecialties is available at: <http://www.abms.org/approved.asp>

may be certified by the American Board of Veterinary Toxicology.<sup>31</sup> The American Board of Toxicology (ABT) was established to provide certification of individuals trained and experienced in toxicology without consideration of whether the individual has a professional Medical or Veterinary Medical degree.<sup>32</sup> However, individuals with an MD, or DVM, degree may also take the ABT certifying examination. A very few individuals are certified by more than one of these boards. Certification by other boards may be relevant for a particular legal case. A person with an advanced degree in toxicology and board certification has strong support for an argument that they are a toxicologist. This may be one reason that the American Association of Veterinary Laboratory Diagnosticians (AAVLD) requires a board certified toxicologist be on staff for an accredited laboratory. A person with an advanced degree but no board certification, or board certification but no advanced degree, may have other criteria to support a finding that they are a toxicologist.

*Do other Criteria Support an Argument that the Person is a Toxicologist?*

Such other criteria may be membership in one or more toxicology organizations, peer-reviewed or other publications, research grants, scientific advisory panels, university appointments and the like (see *Mary Sue Henifin*, p. 418). These criteria are often documented in one's résumé or curriculum vitae.

So, a person with a professional degree, plus an advanced degree in toxicology, plus board certification in toxicology, plus membership in one or more toxicology organizations, peer reviewed toxicology literature, grants, service on scientific advisory panels, and a university appointment has very strong support for an argument that they are an expert in toxicology. On the other hand, a person with a professional degree, no advanced degree in toxicology, no board certification in toxicology and no other publications, grants and the like has a very weak argument, if any, that they are an expert in toxicology. The courts recognize the distinction between a professional degree and expertise required in a legal setting. This distinction is aptly described in *Wynacht v. Beckman Instruments*:

There is a fundamental distinction between Dr. Ziem's ability to render a medical diagnosis based on clinical experience and her ability to render an opinion on causation of Wynacht's injuries. Beckman apparently does not dispute, and the Court does not question, that Dr. Ziem is an experienced physician, qualified

to diagnose medical conditions and treat patients. The ability to diagnose medical conditions is not remotely the same, however, as the ability to deduce, delineate, and describe, in a scientifically reliable manner, the causes of these medical conditions.

Many combinations of education, certification and other criteria that fall between the two above extremes are possible for toxicology experts. These would, of course, be decided by the judge in a specific case. Once found to be an expert, the toxicologist will most likely be asked to give an opinion on general causation.

*General Causation*

"[T]he methodology prescribed by both the World Health Organization (WHO) and the National Academy of Sciences (NAS) for determining whether a person has been adversely affected by a toxin" have been described in *Mancuso v. Consolidated Edison Co.* as a three-step procedure. Scientific validity may be argued in three steps "(1) the validity of the underlying principle, (2) the validity of the technique applying the principle, and (3) the proper application of the technique on a particular occasion" (*Giannelli*, 1980).

First, the level of exposure of plaintiff to the toxin in question must be determined; second, from a review of the scientific literature, it must be established that the toxin is capable of producing plaintiff's illness – called "general causation" – and the dose/response relationship between the toxin and the illness – that is, the level of exposure which will produce such an illness – must be ascertained; and third, "specific causation" must be established by demonstrating the probability that the toxin caused this particular plaintiff's illness, which involves weighing the possibility of other causes of the illness – a so-called "differential diagnosis." (*Mancuso* at 399)

Toxicologists may arrive at an expert opinion in a variety of ways.

The basis of the toxicologist's expert opinion in a specific case is a thorough review of the research literature and treatises concerning effects of exposure to the chemical at issue. To arrive at an opinion, the expert assesses the strengths and weaknesses of the research studies. The expert also bases an opinion on fundamental concepts of toxicology relevant to understanding the actions of chemicals in biological systems. (*Manual on Scientific Evidence*, p. 415)

Two key legal concepts of causation have emerged as courts have attempted to keep junk science out of the courtroom. These concepts are general causation and

<sup>31</sup> [www.abvt.org](http://www.abvt.org)

<sup>32</sup> [www.abtox.org](http://www.abtox.org)

specific causation. The discussion of specific causation follows in the next section.

"Causation is frequently a crucial issue in toxicology cases. Establishing causation means providing scientific evidence from which an inference of cause and effect may be drawn" (Reference Manual on Scientific Evidence, p. 32). The Manual goes on to describe the process of arriving at general causation.

Once the expert has been qualified, he or she is expected to offer an opinion on whether the plaintiff's disease was caused by exposure to a chemical. To do so, the expert relies on the principles of toxicology to provide a scientifically valid methodology for establishing causation and then applies the methodology to the facts of the case.

An opinion on causation should be premised on three preliminary assessments. First, the expert should analyze whether the disease can be related to chemical exposure by a biologically plausible theory. Second, the expert should examine if the plaintiff was exposed to the chemical in a manner that can lead to absorption into the body. Third, the expert should offer an opinion as to whether the dose to which the plaintiff was exposed is sufficient to cause the disease. (Reference Guide on Toxicology, p. 419)

Courts define general causation as "the capacity of a product to cause injury" (*Siharath* at ???). General causation is a scientifically established cause-and-effect relationship. To satisfy this burden, sufficient testing must be done to establish that a disease or condition can arise after exposure to a certain substance. Peer-reviewed literature of epidemiology studies, case reports, *in vitro* and animal studies may be used to support a general causation argument.

A toxic tort plaintiff must first show that the substance to which he was allegedly exposed is capable of causing his injury – general causation (see, e.g., *Raynor* at 7). General causation asks whether exposure to a substance causes harm to anyone.

Increasingly, the discipline of epidemiology is argued as a basis for general or specific causation. When epidemiology is used to present the incidence and distribution of disease in humans, courts have often ruled the expert opinion admissible. This has not always been the case for toxicological expert opinions because of the need to extrapolate from animal, or *in vitro*, studies to humans. This line of argument may be less persuasive in an animal poisoning case when such extrapolations are not needed.

Occasionally experts rely on state or federal regulations to opine that exposure to a certain amount or concentration of a chemical is associated with a particular adverse event. Merely citing the regulation without

further inquiry as to its derivation may erode the strength of such arguments. It may prove critical to the argument to know whether the regulation was established using a "reasonable certainty of no harm" standard or a "normally renders injurious to health" standard.

The former standard may have included various "uncertainty factors" to extrapolate below measured dose-response data to obtain a safety standard. These uncertainty factors may be explored in a legal venue if one is testifying to a "reasonable degree of medical certainty" that the exposure did in fact cause harm, when the basis for the regulatory standard is a "reasonable certainty of no harm" obtained using "uncertainty factors."<sup>33</sup>

In short, is the alleged chemical capable of causing the disease observed at any dose or exposure? In our hypothetical above, has the chemical that was added to the feed additive been shown to cause the clinical signs and lesions observed in the species of animal in this case? If not, the expert's testimony may not be allowed in the case. If so, an analysis of specific causation would be required.

## SPECIFIC CAUSATION – THE DIFFERENTIAL DIAGNOSIS

General causation answers the question of whether the chemical in question may cause the disease observed. Specific causation is aimed at answering the question of whether the chemical in question did in fact cause the disease in the specific case at hand. This concept has been stated in a variety of ways. Specific causation is "proof that the product in question caused the injury of which the plaintiff complains" (*Siharath*). It is a tendency to show that the person's alleged exposure, in fact, caused his or her condition (*Siharath*; see also D.T. Ralston, 2000). In other words, it is a showing that said exposure was the actual cause of the injury (see, e.g., *Raynor*). An analysis of specific causation answers the question of whether exposure to the specific chemical in question did or did not cause the disease experienced by the plaintiff, on in the hypothetical, plaintiff's animals. The specific causation analysis requires consideration of other potential causes of the disease.

Consideration of other causes of the disease is termed the differential diagnosis. The differential diagnosis is a common occurrence in the practice of medicine. Differential diagnosis evidence is often crucial to show specific causation (see *Lennon*). Without some evidence that the substance in question caused the specific injury

<sup>33</sup>See Ellen K. Silbergeld. The role of toxicology in causation: a scientific perspective. 1 Cts. Health Sci. & L. 374, 378 (1991).

to the specific plaintiff, courts are likely to grant the defendant summary judgment. Courts generally agree that, whenever there are different causes for the plaintiff's disease, an expert must perform a differential diagnosis before testimony will be admitted (see *Gianelli*). Courts accept the general validity of the technique of differential diagnosis (*U.S. v. Downing*). An expert opinion based on a properly performed differential diagnosis analysis is not likely to be inadmissible (*Westberry* at 263). More specifically, "[t]o the extent that a doctor utilizes standard diagnostic techniques in gathering this information, the more likely we are to find that the doctor's methodology is reliable" (*In re Paoli* at 758).

Put differently, "[a]n expert who opines that exposure to a compound caused a person's disease engages in deductive clinical reasoning. ...The opinion is based on an assessment of the individual's exposure, including the amount, the temporal relationship between the exposure and disease and other disease-causing factors. This information is then compared with scientific data on the relationship between exposure and disease. The certainty of the expert's opinion depends on the strength of the research data demonstrating a relationship between exposure and the disease at the dose in question and the absence of other disease-causing factors (also known as confounding factors) (Reference Guide, pp. 422–423; see also *Joseph Sanders*, 1994).

However, simply stating that a differential diagnosis was performed is not enough. This issue was discussed in *Viterbo*:

We do not hold, of course, that admissibility of an expert opinion depends upon the expert disproving or discrediting every possible cause other than the one espoused by him. Here, however, Dr. Johnson has admitted that Viterbo's symptoms could have numerous causes and, without support save Viterbo's oral history, simply picks the cause that is most advantageous to Viterbo's claim. Indeed, Dr. Johnson's testimony is no more than Viterbo's testimony dressed up and sanctified as the opinion of an expert. Without more than credentials and a subjective opinion, an expert's testimony that "it is so" is not admissible. (*Viterbo v. Dow Chemical*)

This formulation is repeated by Judge Becker in *United States v. Downing*:

The process of differential diagnosis is undoubtedly important to the question of "specific causation." If other possible causes of an injury cannot be ruled out, or at least the probability of their contribution to causation minimized, then the "more likely than not" threshold for proving causation may not be met. But, it is also important to recognize that a fundamental

assumption underlying this method is that the final, suspected "cause" remaining after this process of elimination must actually be capable of causing the injury. That is, the expert must "rule in" the suspected cause as well as "rule out" other possible causes. And, of course, expert opinion on this issue of "general causation" must be derived from a scientifically valid methodology. (*Cavallo v. Star Enterprise*)

The order of proving causation is important. General causation should be proven first, then the specific causation differential diagnosis analysis. In virtually all cases, differential diagnosis does not provide general causation – it can only provide specific causation.<sup>34</sup> This may be part of the reasoning that argues that epidemiological data are rarely determinative in a specific causation analysis, and are most commonly used in the general causation argument.

To show that said exposure was the actual cause of the injury, toxic tort plaintiffs must prove the admissibility of their expert testimony in both a general causation and specific causation context by a preponderance of proof (*Daubert* at 593). A successful plaintiff must not only show that, more likely than not, the substance can cause the injury in question, but also that, more likely than not, the plaintiff's specific injury was in fact caused by the substance (*DeLuca*; *Ronald J. Allen*, 1991).

A *Daubert* analysis should be performed. In fact, "a trial court that fails to justify its decision not to use *Daubert* factors risks reversal" (*Black v. Food Lion*). *Daubert* factors may be used when assessing the admissibility of clinical medical testimony (*Moore*). This opinion is because reliable opinions are reached using the "methods and procedures of science." Scientific validity is the foundation of "evidentiary reliability" (*Daubert* at 590; see also *Bert Black et al.*, 1994).

So the expert in our case must not only rule in the chemical added to the feed additive as the cause of the clinical signs and lesions observed, but must also rule out other diseases that cause these clinical signs or lesions in that species of animal.

## APPLICATION OF DAUBERT IN TOXICOLOGY CASES

The application of these legal rules to specific toxicology cases may be useful. Testimony may be weakened if there is no *Daubert* inquiry at all (*Goebel*, 2000).

<sup>34</sup>See, generally, *Raynor v. Merrell Pharmaceuticals*, 101 F.3d 129, 138–139 (D.C. Cir. 1996). See also *Kelly*, *Grimes*, *Rutigliano*, *Hall*, *In re Breast Implant*, *National Bank of Commerce* and *Wynacht*.

The differential diagnosis portion of analyzing specific causation is important. Expert testimony from a forensic toxicologist has been properly excluded for insufficient proof to rule in the chemical in question and to rule out other diseases (*Wills*, 2004). The testimony of a toxicologist was properly excluded because the toxicologist was not a medical doctor and therefore not qualified to offer reliable differential diagnosis analysis (*Plourde*, 2003). On the other hand, testimony was properly allowed from two marine biologists who each performed a differential diagnosis analysis in a case involving marine animals (*Clausen*, 2003).

Dose is important in toxicology cases. Testimony of a treating physician, toxicologist and industrial hygienist were excluded, and the exclusion affirmed because the literature did not support a finding of general causation at the relevant exposure (*Amorgianos*, 2002). Testimony of a toxicologist was properly excluded because he performed no dose assessment and showed no statistically significant link between the chemical and the type of cancer present (*Burleson*, 2004).

Reliance on peer-reviewed literature is also important. A toxicologist's testimony was excluded, but the exclusion was reversed, because the toxicologist's testimony was supported by peer-reviewed literature (*Bocanegra*, 2003).

### SOME QUESTIONS TO CONSIDER WHEN USING LABORATORY RESULTS IN A LEGAL CASE

- 1 Was the legal aspect of the case known at the time the samples were submitted? If not, is the sample tracking or chain of custody sufficiently well documented to establish each relevant step of the analysis? Can the relevance of the documents be authenticated? Does chain-of-custody or sample tracking documentation exist?
- 2 What type of legal venue is the work to be used in? Administrative enforcement, civil litigation, criminal litigation? What standard of persuasion is appropriate for this venue?
- 3 Can the relevance of the analytical results be authenticated? What documentation exists that the samples were collected from the appropriate animal? What documentation exists to demonstrate proper sample identification throughout the laboratory testing process? What documentation exists to demonstrate that the process used produces an accurate result – what validation processes are in place? Is the interpretation of the test results accurate for the type of analytical test performed?
- 4 Is the testimony to be as a lay – or fact – witness?

- 5 Is the testimony to be as an expert witness?
  - A Is the expert a toxicologist?
  - B Does the scientific literature support an argument of general causation?
  - C Was a differential diagnosis performed by the laboratory?
    - 1 Rule-in:
      - a Can the expert provide reliable testimony that the sample received by the laboratory is representative of the diseased animals?
      - b Can the expert provide reliable testimony that the animals were in fact exposed to a toxic dose of the chemical in question? To what degree of certainty does the analytical methodology demonstrate exposure of the animal to the chemical in question?
      - c Can the expert provide reliable testimony that the animals experienced the disease expected from exposure to a toxic dose of the chemical in question? Is reliable testimony of the clinical signs and lesions available?
    - 2 Rule-out:
      - a Can the expert provide a differential diagnosis list?
      - b Can the expert provide reliable testimony that the diseases other than the purported one were ruled out? Can the expert explain how and why these other diseases were ruled out? Were scientifically valid methods used to rule out these diseases?

### ACKNOWLEDGMENT

My sincere appreciation to Mr. Kevin Conard, Drs. Roger McClellan, Richard Huston, Beth Thompson, Judith Kashman and federal employees who asked not to be named, for reviewing an early draft of this chapter and providing their valuable insight.

# Nervous system toxicity

Donna Mensching

## INTRODUCTION

The nervous system is a susceptible target for toxicity due to its complex anatomy, specialized functions, high metabolic requirements, limited ability to repair itself and the potential for life-threatening complications when disequilibrium occurs. A plethora of neurotoxins exists including the following: (1) man-made pesticides and agents of chemical warfare that take advantage of this susceptibility, and (2) all-natural compounds that confer advantages to their organisms such as increased predatory efficiency, avoidance of predation or increased survivability of environmental extremes.

As is the case with any toxicant, exposure to a significant dosage of a neurotoxicant warrants appropriate decontamination in an otherwise healthy and asymptomatic patient (see Chapter 104 of this book). In the symptomatic patient, alleviation of clinical signs may be non-specific or symptomatic (e.g., diazepam for seizures) or specifically antidotal based on the mechanism of toxicity (e.g., pralidoxime for organophosphorus insecticides). Table 14.1 lists examples of antidotes used for select neurotoxins. Clinical signs of nervous system toxicity (Table 14.2) can be divided roughly into stimulatory and depressant categories, although overlap of these categories can occur with varying dosages of a given toxicant and/or class of toxicant. When severe signs are not minimized, potential complications can result including extremes of body temperature and blood pressure, hypoxia/anoxia, disseminated intravascular coagulation, rhabdomyolysis, organ failure and trauma resulting from inability to assess the environment and/or inability to avoid environmental hazards.

The general nature of this chapter precludes discussion of every known neurotoxicant. Instead, neurotoxins are divided into those that affect the structural integrity of the nervous system and those that affect only its functional integrity. Keep in mind, though, that functional integrity of the nervous system can be affected by insults to the structural integrity depending on the severity and location of the insult; also the lack of structural changes in functional toxicoses in no way minimizes the potential for a fatal outcome.

## STRUCTURAL TOXICOSES

Histopathological abnormalities associated with structural toxicoses can be subdivided into neuronopathy, axonopathy or myelinopathy. The following discussion addresses each of these pathologies, providing examples relevant to veterinary toxicology.

### Neuronopathy

A neurotoxicant that results in neuronopathy directly targets the neuronal cell body, resulting in cell death and secondary axonal degeneration. Gliosis, proliferation of astrocytes and/or microglial cells, is a common response to loss of neurons (Anthony *et al.*, 2001). With few exceptions, this type of injury is irreversible. Examples of such toxicants include methyl mercury which preferentially targets the cell bodies of the occipital cortex and the cerebellum via an unproven mechanism. Blindness

TABLE 14.1 Neurotoxicants and associated antidotes (Poppenga, 2004; Roder, 2004b,d; Plumb, 2008)

Neurotoxicant(s)	Antidote(s)
Acetaminophen	Acetylcysteine
Amitraz, brimonidine, xylazine	Atipamezole, yohimbine
Benzodiazepines	Flumazenil
Botulinum toxin	Antitoxin
Coral snake	Antivenom
Ethylene glycol	Fomepizole (4-MP), ethanol
Isoniazid	Pyridoxine/vitamin B <sub>6</sub>
<i>Lactrodectus</i> spp.	Antivenin
Lead	Succimer, calcium EDTA, d-penicillamine
Metronidazole	Diazepam
Pyrethroids	Methocarbamol
Opioids	Naloxone
Organophosphorus insecticides	Pralidoxime (2-PAM), atropine
Scorpion	Antivenom
SSRIs/TCAs	Cyproheptadine
Tetanus toxin	Antitoxin

and motor incoordination are common manifestations of lesions in these areas. In veterinary medicine, methyl mercury intoxication is most likely seen in animals that subsist on a diet of contaminated fish. A classic example involves the cats of mercury-contaminated Minamata Bay, Japan, in the 1950s. Due to their advanced cerebellar ataxia, these cats often fell into the water of the bay and were described as “dancing” or “suicidal” (Smith and Smith, 1975; Francis, 1994). In recent years, awareness of environmental contamination with mercury has created biomonitoring programs which attempt to assess the impact of dietary mercury on piscivorous wildlife such as bald eagles (Hinck *et al.*, 2009).

A second example of a toxicant that can directly target neurons of particular relevance in veterinary medicine is the anthracycline glycoside antineoplastic agent doxorubicin (Adriamycin®). Its potential for bone marrow suppression and cardiac toxicity with veterinary use, however, is much greater than its neurotoxic potential (Anthony *et al.*, 2001; Plumb, 2008). Although doxorubicin exerts its antineoplastic effect via interference with transcription, the neurons of the dorsal root ganglia and autonomic ganglia are most susceptible to injury. The selectivity of the effect is thought to be due to a lack of blood–tissue barrier within the ganglia (Anthony *et al.*, 2001).

Domoic acid, the neuronotoxicant responsible for amnesic shellfish poisoning (ASP) in people and wildlife, is produced by the diatom *Pseudo-nitzschia* spp. The toxin is thought to exert its excitatory and cytotoxic effects on hippocampal cells due to its high affinity for binding to the kainate receptor, which is a glutamate receptor subtype. Cellular excitation ensues, resulting in an influx of Ca<sup>2+</sup> ions, up-regulation of the c-Fos gene and cell death (Jeffery *et al.*, 2004). Domoic acid toxicity has been

TABLE 14.2 Signs associated with neurotoxicoses (Podell, 2000)

Stimulatory	Depressant
Hyperactivity	Obtundation
Vocalization	Stupor
Tremors	Coma
Seizures	Ataxia
Hyperesthesia	Paresis/Paralysis
Hypermetria	Abasia
Other:	
Disorientation	
Paresthesia	
SLUDGE (salivation, lacrimation, increased urination, diarrhea, dyspnea, and emesis)	
Cranial nerve deficits (rare)	

responsible for considerable morbidity and mortality of the California sea lion (*Zalophus californianus*; Gulland *et al.*, 2002).

A fourth example of neuronotoxicosis occurs in large animals with yellowstar thistle (*Centaurea solstitialis*) ingestion by horses. This occurs typically in the dry summer and fall and results in neurologic signs including involuntary lip and tongue movements, difficulty in prehending food, tremors, writhing, possible circling, persistent slow movements (dystonia) and significant weight loss. The disease is also called nigropallidal encephalomalacia as a result of the areas of the brain that are uniquely affected (the globus pallidus and the pars reticularis of the substantia nigra). These regions and the clinical signs draw a striking similarity to Parkinson's disease in people (Burrows and Tyrl, 2001; Sanders *et al.*, 2001) which has been associated with selective loss of dopaminergic neurons (van den Munckhof *et al.*, 2006). Of the guaianolide sesquiterpene lactones isolated from *Centaurea* species, cynaropicrin and an analog of solstitialin are cytotoxic in primary cultures of rat substantia nigra cells, and thus raise suspicion for their role in the toxicosis. Aspartic and glutamic acids, two excitatory amino acid neurotransmitters, are also present in *Centaurea* (Burrows and Tyrl, 2001), but their role, if any, in the mechanism of nigropallidal encephalomalacia has yet to be determined.

A final example of a neuronopathic toxicant is currently a common drug of abuse called methylenedioxymphetamine (MDMA) or “Ecstasy.” MDMA selectively targets serotonergic and dopaminergic cells depending on the species exposed, and long-term, irreversible effects may be seen (Gouzoulis-Mayfrank and Daumann, 2006). Acute physiologic effects in people include tachycardia, hypertension, euphoria, heightened sexual awareness, urinary urgency, nausea, chills, sweating and hyperthermia, among others. Signs consistent with serotonin syndrome (hyperactivity, agitation, mental confusion, hyperthermia, tachycardia and

tremors) have been observed in experimentally exposed rats (Easton and Marsden, 2006). Further research is indicated to define species-specific effects, particularly the extent to which serotonergic or dopaminergic neurons are involved. Veterinary practitioners should be aware of the potential for accidental exposure to small animals.

## Axonopathy

The second class of structural lesions caused by neurotoxicants is axonopathy. With damage to the axon, the neuronal cell body remains intact, but the portion of the axon distal to the lesion degenerates, resulting in a "chemical transection" distal to the lesion that is functionally identical to a physical transection of the axon. This is also known as Wallerian or axonal degeneration. Changes in the Nissl substance, the protein synthetic material comprised of free polyribosomes and rough endoplasmic reticulum, become evident histologically in response to this degeneration. These changes include chromatolysis (dissolution of the Nissl substance) as well as margination of the Nissl and the nucleus to the periphery of the cell body. Not surprisingly, those neurons with axons of greatest length are most susceptible to axonal damage. To highlight the susceptibility of distal axons, a subclassification of axonopathy affecting these axons has been termed "central peripheral distal axonopathy." This is in contrast to "central peripheral proximal axonopathy" which involves axons proximal to the spinal cord (Anthony *et al.*, 2001). A third subclassification of axonopathy has been termed "dying back axonopathy." The latter represents progressive death of the axon toward the cell body with time and continued injury. In the peripheral nervous system (PNS), the prognosis for at least partial regeneration is good, but this is less true in the central nervous system (CNS). Secondary demyelination is also possible with axonal injury (Mandella, 2002). Both sensory and motor axons can be affected.

Many agents cause axonopathies, yet just a few are particularly relevant to veterinary medicine. The first example, commonly used as an antineoplastic drug, is the vinca alkaloid vincristine, which is derived from the periwinkle plant, *Vinca rosea* or *Catharanthus rosea*. Vincristine exerts its therapeutic effect by binding to tubulin, inhibiting microtubular formation, disrupting the formation of the mitotic spindle, and arresting cell division at metaphase (Burrows and Tyrl, 2001; Roder, 2004a). Neurotoxicity in the form of axonal degeneration can occur as a result of disruption of fast axonal transport (rate of 400 mm/day normally) which relies on functional integrity of the microtubules (Anthony *et al.*, 2001). Cats are more sensitive to the neurotoxic potential of vincristine. With discontinuation of therapy and appropriate supportive care, animals exhibiting signs of

peripheral neuropathy may improve over several weeks to months (Roder, 2004a). Colchicine, an antimetabolite derived from the autumn crocus (*Colchicum autumnale*) and the glory lily (*Gloriosa* spp.), also inhibits spindle formation (Burrows and Tyrl, 2001; Roder, 2004a). It is used in veterinary medicine for the treatment of amyloidosis associated with Shar Pei fever (Loeven, 1994) as well as hepatic fibrosis (Plumb, 2008). Although reported rarely in humans, no published reports of peripheral neuropathy in veterinary patients were found.

A more common yet fortunately still rare cause of neurotoxicosis in veterinary medicine is metronidazole. A nitroimidazole antibacterial and antiprotozoal agent used to treat *Giardia* and anaerobic intestinal bacterial overgrowth in small animals (Plumb, 2008), metronidazole can result in a sensory peripheral neuropathy manifesting as proprioceptive deficits (Gupta *et al.*, 2000) as well as CNS effects including ataxia, nystagmus, head tilt and seizure activity (Plumb, 2008). Myelinated fibers are most commonly affected (Anthony *et al.*, 2001). The mechanism is unknown for both peripheral and central effects. Oral and/or IV diazepam has been associated with hastened recovery of metronidazole toxicity in dogs (Evans *et al.*, 2003).

A final example of a class of agents that can cause axonopathy are the organophosphorus compounds (OPs), commonly used as insecticides, that can result in signs of neuropathy 7–10 days post-exposure, termed OP-induced delayed neuropathy or OPIDN. An example of historical significance was the delayed neuropathy associated with the intentional contamination of Jamaican ginger alcohol ("Jake") with tri-*ortho* cresyl phosphate (TOCP), an organophosphorus (OP) compound, during the Prohibition years. The TOCP was present in lindol, a substitute solvent added to the Jake to cut costs. The resulting upper motor neuron spasticity and paralysis were irreversible and affected more than 50,000 people (Woolf, 1995). In addition to humans, hens have also been shown to be very sensitive to OPIDN (Damodaran *et al.*, 2001). The neuropathy associated with OPs is thought to involve slow axonal transport macromolecules such as actin and tubulin, which involves movement of the neuronal cytoskeleton at a rate of 1–4 mm/day (Anthony *et al.*, 2001).

## Myelinopathy

Myelin is produced by the oligodendrocytes of the CNS and Schwann cells of the PNS. It is composed of lipid and forms a sheath around certain axons, namely those of the cranial and spinal nerves. It functions to increase the speed of impulse conduction by creating isolated areas of heightened electrical excitability, termed nodes of Ranvier (Spencer, 2000). Myelin gives white matter

its characteristic appearance. Toxicants that result in myelinopathy may affect the myelin itself or target the cells that produce myelin. The insult may result in loss of myelin (demyelination) or edema of the myelin sheath and subsequent separation of myelin lamellae. Remyelination of segmentally demyelinated areas can occur more so in the PNS than the CNS. When peripheral nerves are remyelinated, the process involves more Schwann cells compared to the initial myelination. As a result, the nodes of Ranvier in remyelinated peripheral nerves are closer (Anthony *et al.*, 2001).

Two examples of toxicants that result in intramyelinic edema and separation of the myelin lamellae are hexachlorophene and bromethalin. The former is an antibacterial agent commonly marketed decades ago as pHisoHex<sup>®</sup> and is still commercially available for the treatment and prevention of *Staphylococcal* infections. The latter is a relatively new rodenticide that has been available for roughly 20 years now and is marketed under a variety of trade names including Assault<sup>®</sup>, Sudden Death<sup>®</sup> and Vengeance<sup>®</sup>. The mechanism by which hexachlorophene and bromethalin cause intramyelinic edema is due to the uncoupling of oxidative phosphorylation (Anthony *et al.*, 2001; Dorman, 2004). This uncoupling results in decreased Na<sup>+</sup>/K<sup>+</sup>-ATPase activity, weakened ion gradients and retention of water in the myelin lamellae (van Lier and Cherry, 1988). The use of mannitol or diuretics early in the course of the disease may reverse mild changes, but continued swelling of the lamellae results in a dramatic increase in intracranial and cerebrospinal fluid (CSF) pressure that is typically unresponsive to therapy. Clinical signs in an acute toxic exposure include muscle tremors, hyperthermia, generalized seizures, hyperexcitability, hyperesthesia and death within several hours of ingestion (4–18 h) for bromethalin. Cats are more sensitive to bromethalin than dogs with a minimum lethal oral dose of 0.45 mg/kg versus 2.5 mg/kg in the dog (Dorman, 2004). At lower dosages, hind limb ataxia and paresis can develop in dogs and cats within 2–7 days of ingestion. Signs may include decreased or absent proprioception, loss of response to deep pain, upper motor neuron bladder paralysis, patellar hyperreflexia and varying degrees of CNS depression. These sublethal effects may be spontaneously reversible with time (1–2 weeks). Histologic lesions consistent with bromethalin and hexachlorophene toxicosis include spongy degeneration (diffuse vacuolation) of the white matter of the CNS. Confirmation of a fatal bromethalin toxicosis can be accomplished by identifying the parent compound and/or its more toxic metabolite, desmethylbromethalin, in the liver. Due to their relative inability to metabolize bromethalin into desmethylbromethalin, guinea pigs are resistant to its toxic effects. Treatment of exposed susceptible species is largely aimed at initial decontamination via induction of emesis

(in those species that can vomit) and administration of multiple doses of activated charcoal prior to the onset of clinical signs (Dorman, 2004).

Another toxicant which results in myelinopathy is inorganic lead. The peripheral neuropathic manifestation of lead intoxication is secondary to the segmental degeneration of myelin in distal motor fibers and is most commonly seen in veterinary medicine with chronic intoxication of horses. Sensory function is spared. Clinical signs may include dysphagia and secondary weight loss, ataxia, dysphonia, laryngeal paralysis (“roaring”) and facial nerve deficits. The CNS and other organs may be affected resulting in seizures, depression, secondary aspiration pneumonia, colic and death (Gwaltney-Brant, 2004c).

## FUNCTIONAL TOXICOSES

Most neurotoxicants exert their functional effects via the exquisitely orchestrated mechanisms involved in neurotransmission yet leave no structural footprint of their activity. This can occur at all levels within the nervous system including the CNS, PNS and autonomic nervous system (ANS). Nervous impulses are chemically mediated across synapses by the release of neurotransmitters from the pre-synaptic terminal. These neurotransmitters then move across the synaptic cleft, bind to their post-synaptic target receptor and effect either an excitatory or inhibitory response in the post-synaptic neuron or muscle (Anthony *et al.*, 2001). Functional neurotoxicants may exert their action by preventing synthesis, storage, release, binding, reuptake or degradation of the neurotransmitter. Interference with axonal transmission via sodium, potassium, chloride or calcium channels and subsequent alteration of action potentials can also result in functional toxicoses (Spencer, 2000; Hansen, 2006). Continual development of new pharmaceuticals targeting these endpoints leads to increased likelihood of toxicity in veterinary patients with accidental exposures, particularly in an overdose situation and/or if species differences in pharmacokinetics exist.

Examples of neurotransmitters include acetylcholine; the catecholamine neurotransmitters dopamine, norepinephrine and epinephrine; the amino acid derivatives serotonin (5-hydroxytryptamine; 5-HT), GABA, glycine, histamine, aspartic acid and glutamic acid; and various neuropeptides including enkephalins, substance P (a neurokinin), orexins, endorphins, vasopressin (antidiuretic hormone, ADH) and thyroid releasing hormone (TRH) (Beasley, 1999; Spencer, 2000). The complex array of neurotransmitters provides many targets for neurotoxicity, both by design and unintentional. A more detailed

discussion follows regarding some of the more common neurotransmitters involved in veterinary neurotoxicoses.

## Acetylcholine

Acetylcholine (ACh) is the neurotransmitter that mediates effects at the neuromuscular junction, at the pre-ganglionic neurons of both the parasympathetic and sympathetic nervous systems of the ANS, and at many of the post-ganglionic neurons of the parasympathetic nervous system. It is the target neurotransmitter of OP and carbamate insecticides, which have been marketed since the 1970s and now are widely available commercially for home and agricultural use (Meerdink, 2004b; Gupta, 2006). Acetylcholinesterase (AChE) is the enzyme that degrades ACh to choline and acetic acid within the synaptic cleft. OP and carbamate insecticides bind to AChE, the former by phosphorylating the enzyme, the latter by carbamylating the enzyme, and prevent its degradative action on ACh. This results in an excess of ACh in the synaptic cleft and continued binding to the post-synaptic receptors. Examples of OPs include disulfoton, malathion, terbufos, phosmet, chlorpyrifos, tetrachlorvinphos and parathion. Examples of carbamates include carbaryl, carbofuran, aldicarb, methomyl and propoxur. The onset of action and severity of signs vary widely among these agents. OPs with a sulfur linkage need to be activated by p450 enzymes in the liver prior to exerting their toxic effects, a process which may take just minutes. Carbamates are active upon absorption but some of them are less likely to cross the blood-brain barrier than the more fat soluble OPs. Cholinergic effects are mediated by both muscarinic and nicotinic receptors. Classic muscarinic effects include excess salivation, lacrimation, increased urination, diarrhea, dyspnea (due to increased bronchial secretions) and emesis (abbreviated as the mnemonic SLUDGE or the alternative DUMBELS which stands for diarrhea, urination, miosis, bronchospasm, emesis, lacrimation and salivation). Nicotinic effects include tremors, weakness and paralysis. CNS effects can range from coma and depression to hyperactivity and seizures (Blodgett, 2006).

The main distinction between the OPs and carbamates is the reversibility of the bond between the insecticide and AChE. OPs phosphorylate the esteratic site of the enzyme. At variable times depending on the type of OP bound, the carbon groups attached to the phosphorus are hydrolyzed and replaced by hydrogen. This process is classically referred to as "aging" and represents the point at which there is no possible functional recovery of that enzyme. The use of pralidoxime (2-PAM) as an antidote to preferentially bind the OP is useful only before the aging process has occurred. In contrast, the affinity of carbamates for AChE is much more labile and

aging does not occur with carbamylation of the enzyme. Therefore, the bond between AChE and carbamates is spontaneously reversible with time ( $t_{1/2}$  = 30–40 min) and precludes the use of 2-PAM. Provided the receptor effects are not life-threatening in the meantime, the prognosis for carbamate toxicoses is generally good. With potent carbamates such as methomyl, however, the signs may be severe enough and the duration of effect long enough for the outcome to be fatal. Competitive inhibition of ACh with intravenous (IV) atropine (0.2–0.5 mg/kg,  $\frac{1}{4}$  of dose IV to effect then remainder intramuscular (IM) or subcutaneous (SC)) is indicated for life-threatening bradycardia and/or dyspnea due to bronchospasm and excess bronchial secretions (Plumb, 2008; Blodgett, 2006).

In addition to the chronic OPIDN (discussed under "Axonopathy," above) and the acute toxicosis with SLUDGE effects, there is an intermediate syndrome that is most commonly seen with more lipophilic OPs and classically with chlorpyrifos exposure in cats. It is thought to arise from a down-regulation of muscarinic receptors with sublethal, prolonged exposures. The clinical signs as a result are predominantly nicotinic in nature because those receptors are not down-regulated. Signs which typically appear within 3–10 days of exposure include generalized weakness (including ventroflexion of the neck due to the cat's lack of a nuchal ligament), anorexia, muscle tremors, seizures, depression and/or death (Blodgett, 2006). Due to the reversibility of the bond of AChE with carbamates, the intermediate syndrome is not typically seen. However, it has been uncommonly reported with aldicarb exposures in people (Waseem *et al.*, 2010) and has also been reported with canine aldicarb exposures (ASPCA APCC, unpublished information, 2010).

Another toxicant with muscarinic effects is the mycotoxin slaframine, produced from the fungus *Rhizoctonia leguminicola*, and primarily associated with clovers (*Trifolium* species). It is a cholinergic agonist which is responsible for the clinical picture of profuse salivation or "slobbers" in affected animals (Meerdink, 2004a). Clinical signs consistent with muscarinic stimulation are also seen with ingestion of mushrooms of the genera *Inocybe* and *Clitocybe*, among others, which contain the toxic principal muscarine (Turner and Szczawinski, 1991). Anatoxin-a<sub>(s)</sub>, a neurotoxin produced by the cyanobacteria *Anabaena* sp., *Aphanizomenon* sp. and *Oscillatoria* sp., inhibits AChE in the PNS. Like slaframine, the toxin does not cross the blood-brain barrier (Roder, 2004c).

Several examples of neurotoxicants exist that antagonize muscarinic effects as well. The classic poisonous plant *Atropa belladonna*, or deadly nightshade, is the source of atropine, a racemic mixture of the tropane alkaloids, D- and L-hyoscyamine (Burrows and Tyrl, 2001). Other belladonna alkaloids include scopolamine aka

hyoscyne. *Datura* sp., commonly known as jimsonweed, thorn apple or devil's trumpet, contains scopolamine and hyoscyamine. Excessive anticholinergic action can result in sinus tachycardia, a dry mouth manifesting as increased thirst, dilated pupils, visual disturbances, ileus, urinary retention, restlessness, muscular twitching, incoordination, delirium (as a result of crossing the blood-brain barrier and entering the CNS), respiratory paralysis and death (Burrows and Tyrl, 2001; Pickrell *et al.*, 2004).

Nicotinic cholinergic receptors alone can be involved with neurotoxicoses. Nature has provided several poisonous plants that stimulate these receptors including *Nicotiana* sp. (varying types of tobacco), *Conium maculatum* or poison hemlock and *Lobelia* or Indian tobacco. The numerous alkaloids present in these plants as well as the cyanobacterial toxin anatoxin-a, most commonly produced by *Anabaena flos-aquae* (Roder, 2004c), exert their neurotoxic effects by initially stimulating nicotinic cholinergic and neuromuscular junction receptors but ultimately resulting in a persistent neuromuscular blocking effect. Signs include muscular weakness, tremors, nausea, vomiting, ataxia, tachypnea, tachycardia, hypertension, mydriasis, staggering, seizures, respiratory failure and death (Panter, 2004a, b, c). Treatment is symptomatic and supportive. Prognosis is good except in cases of large overdoses.

Imidacloprid (Advantage®) is a chloronicotinyl nitroguanide insecticide marketed for flea control in pets and which exerts its effects via possibly both agonist and antagonist actions at the nicotinic ACh receptor. Death of the insect is effected via the same clinical signs as previously described above, yet imidacloprid has a wide margin of safety in mammals due to its poor systemic absorption when applied dermally (as labeled) (Craig *et al.*, 2005) and due to the higher affinity of imidacloprid for insect nicotinic receptors versus mammalian receptors. Acute oral ingestions are usually limited to nausea, salivation and vomiting (Wismer, 2004).

Another mechanism by which ACh can be involved in toxicoses is the lack of release of the neurotransmitter from the pre-synaptic terminal. Botulinum toxin, produced by the anaerobic bacterium *Clostridium botulinum*, exerts its action via this mechanism. Sources of the toxin include ingestion of food contaminated with either preformed toxin or clostridial spores, contamination of a puncture wound with spores and ingestion of spores from the environment. Exposure can be oral, inhaled or absorbed cutaneously through devitalized skin (Bailey, 2006). The toxin consists of a 100kD heavy chain and a 50kD light chain linked by disulfide and non-covalent bonds. Upon ingestion of the toxin, its heavy chain binds synaptotagmin, a pre-synaptic vesicle protein. Once the toxin is internalized within the pre-synaptic terminal, its disulfide bonds are cleaved, releasing the light chain. The free light chain is then available to cleave proteins

that are responsible for the docking and release of ACh vesicles into the synapse.

Seven different botulinum toxins (A–G) have been described. Types C and D are most commonly associated with veterinary species (type C is most common in dogs); types A, B, E and F have caused disease in humans. Although differences exist regarding which proteins are cleaved by each toxin type, the end result is the lack of ACh in the synaptic cleft of the neuromuscular junction (Roder, 2004b). The clinical result is a progressive flaccid paralysis which results in death within 3–10 days. Signs are symmetric and progress from the pelvic limbs toward the thoracic limbs. Cranial nerves may be affected, possibly resulting in megaesophagus, decreased jaw tone, facial paralysis and/or a decreased gag reflex. Autonomic functions may be affected as well (Coleman, 1998). The disease is called limber neck in affected birds. In patients that have been supported with artificial respiration, the duration of effect has been documented to persist for 6–8 months (Kotsonis *et al.*, 2001).

The prognosis for severely affected animals is at best guarded but more realistically poor. Treatment can include debridement of wounds, penicillin therapy and antitoxin (5ml IV or IM) within the first 5 days of exposure. Administration of the antitoxin does not reverse the clinical signs attributed to neurons already affected by the toxin. Due to its equine source and antigenicity, an intradermal test dose is recommended prior to full administration IV or IM. For individuals already severely affected, assisted ventilation is indicated until the patient can breathe spontaneously, yet the duration of therapy required may not be practical in veterinary medicine. Extreme supportive care including assisted or parenteral feeding, physical therapy, manual evacuation of the bladder and intermittent manipulation of body position to prevent hypostatic congestion and formation of decubital ulcers is critical. Some laboratories can confirm the diagnosis with analysis of serum, gut contents and/or feed for the preformed toxin (Roder, 2004b; Bailey, 2006). A mouse inoculation assay and type-specific ELISA testing may also aid in the diagnosis of botulism (Thomas, 1991).

### Catecholamine neurotransmitters

Catecholamines are “fight or flight” neurotransmitters that include norepinephrine, epinephrine and dopamine. Their synthesis begins with conversion of the amino acid L-tyrosine to L-dopa. Removal of a carboxyl group from L-dopa forms dopamine which is acted upon by dopamine  $\beta$ -hydroxylase to form norepinephrine (Spencer, 2000). Norepinephrine is also stored in the adrenal medulla and released into the blood with sympathetic stimulation (Capen, 2001). N-methylation of norepinephrine forms epinephrine, an adrenal hormone which is

only nominally present in the brain. Catecholamines are inactivated by monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT) enzymes (Beasley, 1999; Spencer, 2000).

In addition to its role at post-ganglionic sympathetic neurons, norepinephrine also mediates effects in the CNS. Adrenergic receptors include  $\alpha_1$ ,  $\alpha_2$ ,  $\beta_1$  and  $\beta_2$  receptors. Stimulation of  $\alpha_1$  adrenergic receptors, present peripherally, results in vasoconstriction and mydriasis. Stimulation of  $\alpha_2$  adrenergic receptors, present in the CNS, mediates inhibition of norepinephrine, resulting in effects opposite those of  $\alpha_1$  stimulation, namely hypotension. Stimulation of  $\beta_1$  receptors, located predominantly in the heart but also in the kidney, adipose, skeletal muscle and eye, results most notably in an increase in the rate and force of cardiac contraction. The  $\beta_2$  adrenergic receptors (present in skeletal muscles; in the smooth muscle of the bronchi, vasculature and uterus; and also in the liver) mediate vasodilation, bronchodilation, uterine relaxation and enhanced glycogenolysis in the liver (Landsberg and Young, 2001).

Examples of adrenergic toxicosis involving overstimulation of the  $\alpha_2$  receptors include accidental ingestion of brimonidine, the active ingredient in Alphagan® eye drops used in the treatment of glaucoma; ingestion of amitraz-containing Preventic® collars; ingestion of clonidine, a human medication used for hypertension and other indications; and overdosage of the sedative/analgesic xylazine. Exposures involving Alphagan® typically involve puncturing of the bottle with sparing amounts actually ingested. Clinical signs for all four toxicoses include profound hypotension and bradycardia, which can be specifically reversed with either of the  $\alpha_2$  antagonists, yohimbine or atipamezole (Antisedan®). Patients should be closely monitored for recurrence of signs once the effect of the antagonist wears off. The half-life of atipamezole in dogs is longer than yohimbine and may require less frequent administration (Plumb, 2008; Mensching, 2011).

An example of adrenergic toxicosis involving overstimulation of the  $\beta_2$  adrenergic receptors involves the accidental puncture of pressurized albuterol inhalers. Albuterol is a  $\beta_2$  adrenergic agonist used therapeutically to treat the bronchoconstriction associated with asthma. When excessive  $\beta_2$  stimulation occurs, profound hypotension, a reflex tachycardia, and subsequent release of catecholamines can occur. Clinical signs usually include tachycardia with possible ventricular premature contractions (VPCs), tachypnea, hyper- or hypotension (depending on the timeframe relative to exposure and the predominating neurotransmitter effect), behavioral changes including restlessness, agitation, anxiety, largely due to secondary catecholamine release, weakness later in the course, and hypokalemia, sometimes severe, due to an intracellular potassium shift. Treatment is largely supportive with fluid therapy, management of severe tachycardia

with a  $\beta$  blocker such as propranolol, supplementation of potassium as needed and diazepam to address behavioral changes due to secondary norepinephrine release (Mensching and Volmer, 2007).

Sympathomimetics such as amphetamines, cocaine, pseudoephedrine, phenylpropanolamine and ma huang mediate dopaminergic and norepinephrine-induced neurotoxic effects including hypertension, hyperexcitability, tachycardia, tremors, seizures, mydriasis, hyperesthesia, head-bobbing, piloerection and death. Phenothiazine tranquilizers such as acepromazine and chlorpromazine are the mainstay of sympathomimetic overdose therapy due to their post-synaptic blocking effects of dopamine as well as inhibition of its release and increase in its turnover in the CNS. Phenothiazines also block  $\alpha$  adrenergic and cholinergic activity and are antihistaminic (Plumb, 2008; Means, 2004).

## Serotonin

Serotonin (5-hydroxytryptamine) synthesis involves the conversion of the amino acid tryptophan to 5-hydroxytryptophan (5-HTP) followed by the conversion of 5-HTP to 5-hydroxytryptamine. The various physiologic roles of serotonin include regulation of sleep, mood, cognition, appetite and behavior (Spencer, 2000). Due to the popularity of selective serotonin reuptake inhibitors (SSRIs) in human and veterinary medicine and over-the-counter supplements containing 5-HTP for the treatment of depression in humans, accidental overdoses are fairly common in veterinary medicine. Examples of SSRIs include fluoxetine (Prozac®), fluvoxamine (Luvox®), paroxetine (Paxil®) and sertraline (Zoloft®) (Plumb, 2008). The seeds of the West African legume *Griffonia simplicifolia* contain 5-HTP. The clinical picture of serotonin excess, termed serotonin syndrome, includes tremors, seizures, hyperthermia, depression (rarely to the point of coma), disorientation, vocalization, hyperesthesia, ataxia, tachycardia, hypertension, agitation, vomiting and diarrhea. Treatment of the clinical patient is largely symptomatic and supportive, but the serotonin antagonist cyproheptadine specifically mediates the effects of serotonin syndrome. The drug can be given orally or crushed, mixed with water or saline, and administered rectally at a dosage of 1.1 mg/kg in dogs (Gwaltney-Brant, 2004a).

## Glycine

Glycine is an inhibitory neurotransmitter that is synthesized from serine. Glycine acts predominantly in interneurons (Renshaw cells) of the brainstem and spinal cord as well as in spinal sensory, auditory and visual pathways. Two well-known toxicants, tetanus and strychnine, act

by inhibiting glycine's inhibitory effects. Tetanospasmin, a biotoxin produced by the anaerobic bacterium *Clostridium tetani*, is responsible for the prevention of glycine release (Roder, 2004b). The ubiquitous bacterial spores typically enter through a puncture or other anaerobic wound. The lack of glycine inhibition results in unchecked muscle contraction, largely of the powerful extensor muscles of the limbs and the masseter muscles. The stereotypical sawhorse stance and "lockjaw" result within 5–10 days of wound infection. Less severe signs include elevation of the nictitating membrane, which may be the earliest indication of toxicosis in the horse, the most sensitive species (Coleman, 1998). Contracture of facial muscles may result in abnormal wrinkles in the skin, erect ears or an abnormal expression, sometimes referred to as a sardonic grin. Progression of the disease results in an inability to rise and possible seizures. Severe muscular contraction or seizures may be induced by external stimuli. Death is due to an inability of the muscles of respiration to relax and subsequent hypoxia (Roder, 2004b).

Diagnosis of tetanus is based on characteristic clinical signs, history of a wound in which the organism could have proliferated and anaerobic culture of an infected wound. Vaccination with tetanus toxoid is recommended to prevent the disease in horses. Animals with wounds should be treated with penicillin, and the wound should be cleaned routinely to prevent proliferation of the bacteria. A tetanus antitoxin exists but is ineffective for toxin that is already bound and will not reverse existing clinical signs. It can help to prevent progression of the disease, though. The dose for horses and cattle is 10,000–50,000 units SC or IM and 3000–15,000 units for sheep and swine and can be repeated in 7–10 days (Roder, 2004b). Contrary to popular belief, the antitoxin may be extremely cost effective. At the time of this writing, the Colorado Serum Company (Denver, CO) sells 15,000 units for \$22.10 (U.S.) ([www.colorado-serum.com](http://www.colorado-serum.com)). Muscle spasms and seizure activity can be managed by minimization of external stimuli as well as with tranquilizers and muscle relaxants such as acepromazine, diazepam, barbiturates and methocarbamol (Coleman, 1998). The prognosis for severely affected individuals is poor.

Another antagonist of glycine is the neurotoxic bait strychnine, an alkaloid derived from the *Strychnos nux vomica* and *S. ignatii* trees. It binds with high affinity to the glycine receptor and blocks its effects as a result (Patocka, 2009). Extreme muscle rigidity occurs as in the tetanus-intoxicated patient and can rapidly progress to intermittent or continuous seizures within 10–120 min of strychnine ingestion. Anxiety, apprehension, nervousness and tachypnea also may be part of the clinical presentation due to this rapid progression. Death occurs due to hypoxia as a result of contracture of the diaphragm and abdominal and intercostal muscles. The oral LD<sub>50</sub> is

0.5–1.2 mg/kg for dogs; 0.5 mg/kg for horses and cows; 2 mg/kg for cats; and 0.5–1 mg/kg for pigs (Talcott, 2006). In the exposed but asymptomatic patient, aggressive decontamination is warranted. Treatment of the symptomatic patient is limited to symptomatic and supportive care. The agents used to treat muscle spasms, seizures and anxiety in the tetanic patient may also be used in the strychnine-intoxicated patient. The prognosis for symptomatic patients is grave.

## GABA

GABA serves as the predominant inhibitory neurotransmitter in the brain of mammals and is synthesized from glutamic acid. Two main receptor subtypes, GABA<sub>A</sub> and GABA<sub>B</sub>, exist. GABA<sub>A</sub> has at least seven subunits which combine with a chloride channel to form a receptor/ionophore complex. The complex contains binding sites not only for GABA but also for drugs such as the anticonvulsant benzodiazepines and barbiturates. Stimulation of these receptors results in CNS depression, somnolence, fatigue, lethargy, ataxia and muscular incoordination. Paradoxical hyperactivity, excitement or aggression can also occur. In overdoses, CNS and respiratory depression may be extreme leading to hypotension, hypoxia, hypothermia and death (Spencer, 2000; Rudolph *et al.*, 2001).

A discussion of GABA warrants mentioning drugs of the avermectin class, commonly used in veterinary medicine for the prevention of heartworm disease (*Dirofilaria*) in dogs and cats; the treatment of endoparasitism (strongyles, ascarids, bots, threadworms, lungworms, stomach worms and summer sores (*Habronema*, *Draschia* species)) and ectoparasitism (*Sarcoptes*, *Demodex*). Examples of avermectins include ivermectin (Heartgard®), selamectin (Revolution®), milbemycin (Interceptor®), moxidectin and abamectin. Their mechanism of action on target species was thought to be due to the enhanced release of GABA at pre-synaptic neurons, causing parasite paralysis and eventual death (Plumb, 2008). Mealey (2006), however, reports evidence that suggests the target effects to be mediated via glutamate-gated chloride channels in the CNS. Such channels are not present in the mammalian brain, allowing for a wide margin of safety of these drugs in the host animal. Furthermore, in genetically healthy animals, p-glycoprotein, part of the blood–brain barrier, is present in the apical membrane of brain capillary epithelial cells, and serves as an efflux pump to remove avermectins from the brain (Mealey, 2006).

Significant clinical signs can be seen, though, in an acute or chronic avermectin overdose, particularly with a dog that has a p-glycoprotein defect or MDR1 mutation. They include ataxia, CNS depression (potentially to the

point of coma), recumbency, disorientation, mydriasis/apparent blindness, muscle tremors, seizures, respiratory depression, hypothermia, bradycardia, hypoxia and death. The onset of signs is expected to be more rapid and the severity of the clinical picture more extreme in the p-glycoprotein deficient dog. Signs may persist for weeks, but the duration of effect is often difficult to predict based on the severity of signs. Extreme supportive care is indicated for the comatose patient. Assisted ventilation may be necessary. Repeated doses of activated charcoal can be of significant benefit due to the enterohepatic recirculation of avermectin drugs. In recent years, treatment of moxidectin toxicity with an emulsion of intravenous lipids indicates that it may be an effective way to hasten elimination of fat-soluble toxicants (Crandell and Weinberg, 2009). If treated aggressively, with or without intravenous lipids, severely affected dogs can recover without long-term sequelae (Mealey, 2006; Merola *et al.*, 2009).

A unique example of neurotoxicity in the dog relates to a species difference in metabolism. Isoniazid, an antibiotic used in the treatment of tuberculosis, is metabolized by acetylation via the enzyme N-acetyltransferase. Dogs are poor acetylators and, therefore, cannot effectively metabolize the drug. Isoniazid forms a complex with pyridoxine (vitamin B<sub>6</sub>), creating a pyridoxine deficiency. Synthesis of GABA requires the cofactor pyridoxal phosphate. In the absence of sufficient cofactor, the inhibitory neurotransmitter is not made and seizures ensue. Emergency treatment involves IV administration of pyridoxine at a dose equivalent to the mg of isoniazid ingested, if known. Supportive care with fluid therapy is indicated, as may be adjunctive diazepam or other anti-convulsants, particularly if the pyridoxine is not immediately available (Villar *et al.*, 1995).

## Glutamate/aspartate

The primary excitatory neurotransmitters of the brain are the non-essential amino acids glutamate and aspartate. Their synthesis in the brain from glucose and other molecules is tightly regulated. The blood-brain barrier excludes excesses of these excitatory neurotransmitters except in areas of the hypothalamus (arcuate nucleus) and retina where acute cellular degeneration may occur as a result. Three main receptor subtypes exist for glutamate: AMPA (DL- $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid), kainate (KA) and NMDA (N-methyl-D-aspartate) receptors. As previously mentioned (see "Neuronopathy," above), domoic acid is an example of a toxicant that stimulates kainate receptors (Jeffery *et al.*, 2004).

As previously mentioned, glutamate and aspartate may play a role in the pathogenesis of yellowstar

thistle intoxication in horses (Spencer, 2000). The plant is known to contain both excitatory amino acids in addition to several unstable guaianolide sesquiterpene lactones which may degrade to the former to exert their neurotoxic effects (Burrows and Tyrl, 2001).

A limited number of drugs used in veterinary medicine are NMDA antagonists. Ketamine, a dissociative anesthetic used commonly for induction of general anesthesia, blocks the open NMDA ion channel by binding to it. Seizures, due to elevation of CSF pressure, are a potential sequela of ketamine use at therapeutic doses. Amantadine, an antiviral drug that is an NMDA antagonist, is being used in the management of chronic pain. Particularly in the early course of treatment, stimulatory signs in dogs such as agitation may be seen. Seizures, tremors and psychosis have been reported in relatively small overdoses in people (Plumb, 2008).

## Histamine

Histamine is a physiologically active amine that is both a neurotransmitter as well as a mediator of peripheral effects relating to allergic reactions and gastric acid secretion. It is formed from the decarboxylation of L-histidine. Peripherally, histamine receptors are of two subtypes: H<sub>1</sub> and H<sub>2</sub>. The former mediate allergic reactions in which histamine is released from the granules of mast cells, resulting in dilation and increased permeability of capillaries (wheal and flare reaction) and constriction of bronchial smooth muscle. The H<sub>2</sub> receptor stimulation increases gastric acid secretion (Gwaltney-Brant, 2004b).

Antagonists of H<sub>1</sub> receptors are commonly used to treat acute and chronic allergic reactions, to prevent mast cell degranulation during surgical excision, as well as to minimize motion sickness in veterinary and human medicine. They are divided into first- and second-generation antagonists. The first-generation antihistamines can both stimulate and depress the CNS while the second-generation antihistamines are considered non-sedating due to their exclusion from the brain at therapeutic dosages. At therapeutic doses and with mild overdoses, particularly with the first-generation antihistamines, CNS depression and hypotension may be seen. Epinephrine is contraindicated for management of hypotension in these patients. Paradoxical CNS excitation including restlessness, hyperactivity, tachycardia, tremors and seizures may also occur and the potential for it varies largely with the individual. Large overdoses of either antihistamine class can result in extreme CNS and cardiovascular (CV) stimulation to the point of seizure activity, cardiac arrhythmias, hypertension and death. Seizures, tremors and hyperactivity may be treated with diazepam or barbiturates (Gwaltney-Brant, 2004b).

Common H<sub>2</sub> blockers used in veterinary medicine to decrease gastric acidity include cimetidine, ranitidine and famotidine. Of the H<sub>2</sub> blockers, cimetidine is more likely to cross the blood–brain barrier. Adverse effects are rare in veterinary patients (Plumb, 2008).

### Mixed neurotransmitter effects

Many pharmaceuticals and toxicants exert their effects through multiple neurotransmitters. One example group is the many ergot alkaloids produced by fungi of the *Claviceps* genus. The mycotoxins can be further divided into ergopeptine and ergoline alkaloids. The alkaloids exert their toxic effects via effects on dopaminergic, serotonergic and adrenergic pathways. Successful recovery is aimed at early diagnosis, when signs such as ataxia and confusion are reversible, and removal of the contaminated feed source (Evans *et al.*, 2004). The effects of the ergoline alkaloids, in particular, can also be seen with ingestion of the seeds of *Ipomoea* or morning glory and are very similar to those of the related street drug lysergic acid diethylamide, also known as LSD (Burrows and Tyrl, 2001).

$\alpha$ -Latrotoxin, the toxin in the venom of the black widow spider (*Latrodectus*), causes the release of catecholamine neurotransmitters as well as ACh, GABA and glutamate. The toxin mediates its catecholamine effects by forming a transmembrane pore through which Ca<sup>2+</sup> can influx, allowing release of pre-synaptic vesicles containing neurotransmitters. Clinical signs associated with a bite from *Latrodectus* species include abdominal pain, ataxia, muscle fasciculations, muscle rigidity and flaccid paralysis, which can ascend to involve the respiratory muscles. Cats are more sensitive than dogs to the effects of  $\alpha$ -latrotoxin, but all mammalian species are susceptible. Antivenin is commercially available for black widow spider bite victims. Like all products derived from equine serum, a test dose should be administered intradermally to determine if hypersensitivity to the product exists. If none exists, the contents of the antivenin vial (2.5 ml) can be diluted 4–20  $\times$  (10–50 ml) with sterile saline and administered slowly intravenously over approximately 15 min. A slow, IV injection of 10% calcium gluconate may be given to treat the muscle fasciculations and weakness as well. Aggressive pain management with opioids or benzodiazepines is indicated (Roder, 2004d).

## ION CHANNELS

The propagation of an impulse along an axon depends on an electrochemical gradient that is intricately regu-

lated by various ion channels in an excitable membrane. Initiation of action potentials, release of neurotransmitters, axonal transport and healthy muscle activity rely on control of ions such as sodium, potassium, chloride and calcium (Spencer, 2000). Specific veterinary examples follow regarding the variety of natural and synthetic toxicants that target the ion channels of the nervous system.

### Sodium channels

The sodium channel of mammals is made up of three protein subunits, the largest of which is the transmembrane  $\alpha$  ( $\alpha$ ) subunit which contains the Na<sup>+</sup> pore and which is flanked by two smaller  $\beta$  subunits. The pores are voltage-gated, allowing sodium ion entrance into the cytoplasm only when charge-dependent conformational changes occur. Nature provides us with several examples of neurotoxicants which affect the sodium channel. Tetrodotoxin (TTX), present in various genera of puffer fish, in the venom of the blue-ringed octopus (*Hapalochlaena* spp.), the rough-skinned newt (*Taricha* spp.) and many other creatures, exhibits a profound binding affinity for the sodium channel peptide complex. Whereas the Na<sup>+</sup> ion normally reversibly binds to the peptide complex for just nanoseconds, TTX binds to the external surface of the peptide ion channel, remains bound for tens of seconds and halts the action potential. A progression of signs occurs with TTX poisoning in people: (1) initial numbness around the mouth with or without nausea; (2) numbness of the tongue, face and skin, early motor paralysis and incoordination manifested as slurred speech; (3) more widespread paralysis resulting in dyspnea, hypotension, an inability to speak and fixed and dilated pupils; and (4) severe paralysis involving respiratory muscles, hypoxia, hypotension and cardiac arrhythmias. Consciousness may be lost followed by death due to respiratory failure as early as 17 minutes after ingestion or as late as 24 hours. No antidote currently exists. Treatment is aimed at decontamination and symptomatic and supportive care (Kaku and Meier, 1995; White, 1995).

Saxitoxin, the causative toxin for paralytic shellfish poisoning (PSP), is produced by several dinoflagellates, most notably *Alexandrium* and *Pyrodinium* species, and causes a similar clinical picture as that of TTX toxicosis also due to binding to the sodium ion channel (Smart, 1995).

Local anesthetics exert their pharmacologic effects by binding to the fast sodium channel complex when it is inactive, inhibiting its recovery after depolarization. Lidocaine, as an example, rapidly dissociates from the sodium channel complex and is also rapidly metabolized in the liver. Consequently, adverse events associated with therapeutic dosages are rare. In an overdose

situation, however, CNS depression, ataxia, seizures and circulatory collapse can occur (Welch, 2000; Plumb, 2008). Dibucaine HCl is 10 times more potent than lidocaine and much more likely to result in adverse effects as a result. Cats are especially susceptible to the methemoglobinemic potential of local anesthetics. Treatment of clinical signs is largely symptomatic and supportive, aimed at maintenance of blood pressure, addressing cardiac arrhythmias and management of seizures (Welch, 2000). The experimental report of bupivacaine-intoxicated dogs successfully treated with intravenous lipid emulsion (Weinberg *et al.*, 2003) holds promise for future use with local anesthetic toxicoses.

Several toxins affect the sodium ion channel by enhancing its activity, resulting in repetitive and prolonged neurotransmission. Brevetoxins, produced by the dinoflagellates *Karenia brevis* and *Gymnodinium breve*, prolong the opening of the sodium ion channels, perpetuating the propagation of the action potential. Bossart *et al.* (1998) implicated the toxin in the death of a minimum of 149 manatees along the southwest coast of Florida in 1996. Another example are ciguatoxins which are produced by dinoflagellates and are bioaccumulated by herbivorous, and then piscivorous, fish. They enhance  $\text{Na}^+$  permeability through the ion channel (Spencer, 2000). The hallmark clinical sign of ciguatera fish poisoning (CFP) in people, and presumably in affected veterinary species, is a paresthesia (tingling sensation) in the extremities as well as a perception of heat with cold stimuli ("dry-ice phenomenon") (Kaplan, 2000). The neurologic signs are attributable to edema of the adaxonal Schwann cell cytoplasm and can persist for weeks. Gastrointestinal pain and diarrhea are also typical, particularly in the early course of the disease (Glaziou *et al.*, 1995; Spencer, 2000).

Other examples of toxicants that block inactivation of sodium channels include batrachotoxin, a steroid alkaloid isolated from the skin of *Phylllobates aurotaenia* and other species of South American poison dart frogs (Spencer, 2000); grayanotoxins, diterpene alkaloids from the plants of the *Rhododendron*, *Kalmia*, *Pieris*, *Leucothoe* and *Lyonia* genera (Puschner, 2004); aconitine, present in monkshood (*Aconitum* spp.); and veratridine from *Veratrum album* (Spencer, 2000). Both  $\alpha$ -scorpion and  $\beta$ -scorpion toxins bind to  $\text{Na}^+$  channels, albeit different sites, and enhance nerve conduction. Toxins of the Sydney funnel web spider (*Atrax robustus* and *Hadronyche* species;  $\delta$ -atraxotoxin, atraxotoxin, robustoxin) also block sodium channel inactivation. Persistent neuronal excitation with all of these toxins can result in a tingling sensation, muscle spasms, agitation, seizures, cardiac arrhythmias and death potentially within an hour of exposure (White *et al.*, 1995; Spencer, 2000).

Pyrethrins, natural organic esters isolated from the flower of the *Chrysanthemum cinerariaefolium*, have

natural insecticidal properties as a result of their ability to bind to  $\text{Na}^+$  ion channels and slow their inactivation. These natural insecticides have a rapid knockdown effect of the insect followed by recovery. Synthetic analogs, pyrethroids, were developed to increase the insecticidal potency. Because of their relatively rapid metabolism, pyrethrins and pyrethroids are often marketed with synergists such as MGK-264 or piperonyl butoxide to inhibit enzymes which degrade them, thereby prolonging their insecticidal action. Today, pyrethroids are common ingredients in flea and tick spot-on products and sprays. Examples include permethrin, phenothrin, tetramethrin, fenvalerate, cyhalothrin, cyfluthrin, cypermethrin, cyphenothrin and etofenprox (Volmer, 2004; Merola and Dunayer, 2006).

Fish and cats represent the most susceptible animals to pyrethroids. Fish typically die acutely when exposed to pyrethroids. Cats are most commonly presented to the veterinarian as a result of exposure to the highly concentrated (45–65%) spot-on permethrin products labeled for use in dogs. Within 12–18h of application or accidental exposure, affected cats will exhibit hyperesthesia, generalized tremors, hyperthermia, seizures and possible death. The prognosis for complete recovery, however, is excellent with appropriate care. Seizures should be controlled with diazepam, barbiturates, inhalant anesthetics or intermittent propofol (caution regarding including Heinz body formation in cats with propofol). Tremors should be controlled with slow IV injection of methocarbamol (55–220mg/kg) to effect. Once severe tremors and seizures have been treated, decontamination with a warm bath using a liquid dishwashing detergent is indicated. Thermoregulation is critical. Hyperthermia can arise with continued tremors and seizures and could result in life-threatening disseminated intravascular coagulation. Hypothermia can ensue following a bath and can enhance or prolong the toxicosis. Supportive care with IV fluids can help protect the kidneys from myoglobinuric damage. Other species may have dermal hypersensitivity reactions or local paresthesia effects from topical application of pyrethroids. Steady resolution with this clinical picture is expected once the dermal residue is removed post bathing (Volmer, 2004; Hansen, 2006).

## Potassium channels

Potassium channels are largely involved with repolarization of the neuron following  $\text{Na}^+$ -induced depolarization. The opening of these potassium channels is voltage dependent and allows  $\text{K}^+$  to leave the cell, thereby restoring the resting potential of the axonal membrane. Several subtypes of potassium channels exist, the details of which exceed the scope of this text. Clinical effects of potassium channel-blocking toxicants

or adverse effects of similarly acting therapeutic agents depend on the type of  $K^+$  channel and location. A potent example of a potassium channel blocker in veterinary medicine is 4-aminopyridine (4-AP; Avitrol®). Predominantly used as an avicide, 4-AP ingestion by birds results in rapid onset of seizures and death (Schell, 2004). Although its classification as a 1A antiarrhythmic indicates it primarily blocks  $Na^+$  channels, quinidine, derived from the *Cinchona* tree, also blocks potassium channels. Depression, confusion and seizures are possible with quinidine overdose (Plumb, 2008). Classified as a class III (potassium channel blocker) antiarrhythmic, amiodarone also has sodium and calcium channel blocking effects. Adverse effects include bradycardia and hypotension and potentially hepatopathy but not primary nervous system effects. Sotalol, also a class III antiarrhythmic, exerts its pharmacological effect via blockade of cardiac potassium channels. It also has beta-blocking properties. Like amiodarone, adverse effects are primarily cardiac (bradycardia and hypotension), but nervous system effects secondary to hypoglycemia are also possible (Plumb, 2008).

### Chloride channels

As opposed to sodium and potassium channel neurotoxins, relatively few toxins have been identified that affect the chloride channel. Chloride ions can diffuse passively down their concentration gradient out of the neuron. Chloride ion channels regulate the entrance of chloride into the neuron and affect the membrane potential as a result. Normal resting membrane potential is 270mV. Threshold potential, the potential at which an action potential is propagated, is roughly 250mV. Membranes can be hyperpolarized by allowing entrance of negative chloride into the neuron and making it more difficult to reach threshold potential. Both benzodiazepines and barbiturates mediate their effects via GABA<sub>A</sub> receptors which are chloride ionophore complexes (Crystal and Schaumburg, 2000). Minute details regarding binding sites, duration and frequency of chloride channel opening effected by barbiturates and benzodiazepines have been extensively studied (Hobbs *et al.*, 1996; Crystal and Schaumburg, 2000; Maytal and Shinnar, 2000), yet the exact mechanism remains unclear. Ultimately, the two classes of drug inhibit excitatory neurotransmission by increasing chloride conductance into the neuron.

The use of potassium bromide for chronic management of idiopathic epilepsy in veterinary patients is based on the competition of the bromide ion with chloride ions for transport across cell membranes. The therapeutic action relies on hyperpolarization of the neuronal membrane and a decrease in the propagation of epileptic discharges. Bromide blood levels should be monitored routinely in treated animals and particularly in those

animals exhibiting signs of bromide toxicity. Neurologic signs consistent with a bromide toxicosis include ataxia, tremors and sedation to the point of stupor in veterinary species (Plumb, 2008). Headache, mood alterations, hallucinations, speech abnormalities and visual disturbances have also been reported with human bromism (Spencer, 2000). Because bromide has a longer half-life than chloride, the latter is preferentially excreted by the kidney. In animals with a deficiency of dietary salt, the half-life of bromide is prolonged, enhancing the chances of neurotoxicity. Conversely, the epileptic patient with a high dietary salt intake may have seizure activity that is poorly managed with potassium bromide treatment (Plumb, 2008).

## OTHER MECHANISMS OF NEUROTOXICITY

Knowledge of the nervous system is continually expanding. Whereas the mechanisms of action of neurotoxins discussed thus far have been simplified to affect one neurotransmitter or ion channel, the reality is likely far more complex. Additionally, clinicians should be aware of metabolic factors that can exacerbate neurotoxins. Examples of these factors include acidosis, hypoglycemia and hepatic encephalopathy. Increased carbon dioxide, which readily diffuses across the blood-brain barrier, can cause narcosis by affecting neurotransmitters as well as increasing intracranial pressure. Compensation for hypercapnea with hyperventilation is the reason that metabolic acidosis is less likely to contribute to encephalopathy than respiratory acidosis (Dewey, 2008). Monitoring of acid-base status, volume restoration, correction of metabolic acidosis with sodium bicarbonate as needed (Plumb, 2008) and assisted ventilation when necessary are means by which these potential complications can be minimized.

Hypoglycemia can be a primary effect of neurotoxins as with sulfonylurea medication overdoses or xyli-tol ingestion in dogs (Meadows, 2011) or a secondary effect with increased glucose utilization in the patient with refractory seizures. Signs of neuroglycopenia occur when blood glucose goes below 45mg/dl and include weakness, ataxia, collapse, restlessness, tremors, seizures, blindness and potentially changes in behavior (Podell, 2000; Nelson, 2009). Hypoglycemia can be corrected with administration of intravenous dextrose to effect (Meadows, 2011).

Finally, hepatic encephalopathy can result in neurotoxicity as a result of the inability of the liver to clear the body of toxins, namely ammonia, and the brain's sensitivity to it. Alterations of serotonin, GABA and glutamine and stimulation of NMDA and

benzodiazepine receptors ensue which are responsible for potential disorientation, gait disorders, behavioral changes and/or seizures (Watson and Bunch, 2009). Treatment with lactulose to lower blood ammonia, appropriate antibiotics, supportive care and management of seizure activity are indicated (Webster, 2011).

## CONCLUSIONS

The health of the nervous system, and largely that of the individual, relies on the system's structural and functional integrity. From specialized nerve cells and anatomic structures to axonal transport, myelination, neurotransmitter synthesis, storage, release, binding and degradation as well as the regulation of action potentials,

maintenance of nervous system integrity is a complex task requiring significant energy expenditure. This functional complexity and structural specialization provide a plethora of targets for neurotoxicant action. The scope of this chapter precludes a detailed discussion of every known neurotoxicant. Many more mechanisms exist by which neurotoxicants exert their effects. Table 14.3 provides a comprehensive, yet certainly not exhaustive, list of neurotoxicants grouped by mechanism or site of action, where known.

The extent to which a neurotoxicant exerts its effects depends on a variety of factors including dose, species, age, genetics, underlying diseases, drug therapy, diet, stress and concurrent toxicoses. Veterinary practitioners should be aware of these underlying susceptibilities and the most common mechanisms by which neurotoxicants act so that toxicoses may be avoided or appropriately diagnosed and successfully treated when they do occur.

TABLE 14.3 Neurotoxicants arranged by mechanism of action (Beasley, 1999; Spencer, 2000; Burrows and Tyrl, 2001; Schulze, 2002; Plumlee, 2004)

### Mediation by acetylcholine

*Amanita muscaria* (minute amount)  
Anatoxin-a  
Anatoxin-a<sub>(s)</sub>  
*Atropa belladonna*/atropine  
Botulism  
Carbamate insecticides  
*Clitocybe* mushrooms  
*Conium maculatum* (poison hemlock)  
*Datura* (jimsonweed)  
*Gymnocladus dioica* (Kentucky coffee tree)  
Imidacloprid  
*Inocybe* mushrooms  
*Lobelia* (Indian tobacco)  
Nicotiana  
Organophosphorous insecticides  
Slaframine

### Mediation by norepinephrine

Albuterol  
Atipamezole  
Atomoxetine  
Brimonidine  
Clonidine  
Doxazosin  
Medetomidine  
Metoprolol  
Monoamine oxidase inhibitors (MAOIs)  
Propranolol  
Phentolamine  
Phenoxybenzamine  
Sotalol  
Tamsulosin  
Terazosin  
Tricyclic antidepressants (TCAs)  
Venlafaxine  
Yohimbine  
Xylazine

### Sympathomimetics/catecholamines

Amphetamines  
Cocaine  
Ma huang (*Ephedra*)  
MDMA/"Ecstasy"  
Monoamine oxidase inhibitors (MAOIs)  
Phenylpropanolamine  
Pseudoephedrine  
Tricyclic antidepressants (TCAs)

### Mediation by serotonin

Amphetamines  
*Griffonia*/5-HTP supplements  
Lysergic acid diethylamide (LSD)  
MDMA/"Ecstasy"  
*Phalaris* (Canary grass poisoning)/tryptamine alkaloids  
*Psilocybe* mushrooms  
Selective serotonin reuptake inhibitors (SSRIs)  
Tricyclic antidepressants (TCAs)  
Tryptophan  
Venlafaxine

### Mediation by glycine

*Calycanthus* (bubby bush)  
Strychnine  
Tetanus  
Tremorgenic mycotoxins (penitrem A and roquefortine)

### Mediation by GABA

Avermectins  
Baclofen  
Barbiturates  
Benzodiazepines  
Bicuculline  
*Cicuta* (water hemlock)  
Cyclodiene organochlorines  
Fipronil  
Flumazenil  
Isoniazid

(Continued)

TABLE 14.3 (Continued)

<b>Mediation by glutamate/aspartate</b>	Non-protein nitrogen
Amantadine	NSAIDs
+/- <i>Centaurea solstitialis</i> (yellowstar thistle)	Pyrrolizidine alkaloids:
Domoic acid	<i>Senecio</i>
Ketamine	<i>Crotalaria</i>
<b>Mediation by histamine</b>	<i>Heliotropium</i> (giant hog weed)
Brompheniramine	<i>Amsinckia</i> (fiddle neck, tarweed)
Chlorpheniramine	<i>Symphytum</i> (comfrey)
Cetirizine	<b>Stimulating cannabinoid receptors</b>
Cimetidine	<i>Cannabis sativa</i> (marijuana)
Cyproheptadine	<b>Mediation of opioid receptors</b>
Dimenhydrinate	<i>Aesculus hippocastanum</i> (horse chestnut)
Diphenhydramine	Buprenorphine
Famotidine	Butorphanol
Fexofenadine	Codeine
Hydroxyzine	Fentanyl
Loratadine	Heroin
Ranitidine	Hydromorphone
Scombroid fish poisoning	Loperamide
<b>Effect on sodium channels</b>	Meperidine
Aconitine	Morphine
Batrachotoxin	Naloxone
Brevetoxins	Oxymorphone
Ciguatoxin	Oxycodone
Funnel web spider toxins	Tramadol
Grayanotoxins	<b>Multiple/miscellaneous MOAs</b>
Local anesthetics	<i>Ageratina</i> (white snakeroot): tremetone
Pyrethroids	<i>Astragalus/Oxytropis</i> (locoweed): miserotoxin
Saxitoxin	Bovine bonkers/ammoniated feed): 4-methylimidazole
$\alpha$ and $\beta$ scorpion toxins	<i>Brunfelsia</i> (yesterday, today and tomorrow plant): brunfelsamidine
Sodium intoxication	<i>Cycas</i> (sago palm): $\beta$ -methylamino-L-alanine
Tetrodotoxin	5-Fluorouracil/1080
Veratridine	Lead
<b>Effect on potassium channels</b>	<i>Macrozamia</i> (cycad palms): $\beta$ -oxalylamino-L-alanine
4-Aminopyridine	Mercury
Amiodarone	Methylxanthines, <i>Guarana</i> (adenosine receptor antagonists)
Quinidine	Phenothiazines (anticholinergic, antihistaminic, $\alpha$ -adrenergic blocking effects)
Sotalol	<i>Sorghum</i> (Sudan grass): $\beta$ -cyanoalanine
<b>Effect on chloride channel</b>	<i>Stipa</i> (sleepy grass): ergot alkaloids
Avermectins	<b>Metabolic</b>
Barbiturates	Carbon monoxide
Benzodiazepines	Cyanide
Picrotoxin	Zinc phosphide
Potassium bromide	<b>Thiamine deficiency/thiaminase excess</b>
<b>Producing acidosis</b>	<i>Equisetum</i>
Aspirin	<i>Pteridium</i> (bracken fern)
Ethanol	Raw fish diet
Ethylene glycol	Excess dietary sulfur
Metaldehyde	<b>Uncoupler of oxidative phosphorylation</b>
Methanol	Bromethalin
<b>Causing hypoglycemia</b>	Hexachlorophene
<i>Xanthium</i> (cocklebur)	Trialkyltin
Sulfonylureas	<b>Unknown etiology/MOA</b>
Xylitol	Desert spike
<b>Producing hepatic encephalopathy</b>	Diethyltoluamide (DEET)
Acetaminophen	Essential oils
Alsike clover (horses)	Hydrocarbons
Blue-green algae (microcystins)	Indoxacarb
<i>Cycas</i> (sago palm): cycasin	Macadamia nuts
<i>Lantana</i>	Nitrofurantoin
<i>Macrozamia</i> (cycad palms)	Tick paralysis
D,L-Methionine

## Respiratory toxicity

John A. Pickrell and Deon van der Merwe

### INTRODUCTION

The respiratory system is relevant in toxicology as a target of toxic effects, and also as a major route of absorption of inhaled gases and atmospheric particles. If inhalation and subsequent absorption reach a toxic threshold, inhaled chemicals have the potential to produce lung disease. If the chemical is trans-located to other organs, disease can be produced in those organs. As a highly perfused organ system, the respiratory system is also a potential target for toxic chemicals in the blood circulation, irrespective of the route of absorption. Inhalation toxicology refers to the respiratory system as a route of exposure. In contrast, respiratory toxicosis refers to respiratory organ toxicosis. The environments in which animals live are directly relevant to respiratory toxicosis (Pickrell, 1991). Different species may have anatomical features that lead to specific patterns of deposition and absorption of chemicals from the air, resulting in species variations in adverse effects (Morris *et al.*, 1986).

To understand respiratory toxicosis we need understanding of (1) toxicant dose delivered to specific sites of the lung and (2) the effects of toxicants on respiratory system tissues under conditions of acute and chronic exposures. Many lung diseases have their beginnings with increases in oxidative lung burden. There is strong evidence that oxidative lung burden may favor development of lung diseases such as bronchitis, asthma and interstitial lung disease (Witschii and Last, 2001).

Advances in lung toxicology are augmented by interdisciplinary collaboration between anatomists, physiologists, immunologists, pathologists, molecular biologists, epidemiologists, clinicians and many other shared disciplines. Adaptation of pulmonary function

tests to animals has led to the comparison of human and animal data, generally providing more robust conclusions compared to data from single species. Recent molecular measurements have brought home how closely tied many of these diseases are to specific protein changes. Such molecular analyses help to pinpoint specific molecular reactions to specific cell types. In addition, they help us describe the more relevant influence of each cell on the others in the near neighborhood. Tissue culture, organ minces and *in vivo* animal exposure studies, such as broncho-alveolar lavage washings, further elucidate these interactions.

### THE UPPER AIRWAYS

#### Normal function

The nasopharynx is lined by pseudostratified columnar ciliated epithelium with goblet cells (Dungworth, 1993). Abundant lymphoid nodules are present in the submucosa. The eustachian tubes extend from the middle ear to the nasal cavity. Many animals, including horses and small laboratory rodents, are obligate nose breathers. Other animals can breathe through either their nose or mouth.

The mucous membranes of the nasal passages produce secretions from serous and mucous glands, which produce mucopolysaccharides and mucoprotein, and goblet glands, which produce similar, but sulfated, secretions. Ciliated epithelium covers a capillary net providing a rich blood supply. Mucous secretions protect the mucous membranes, and can retain particulate matter and

substances that dissolve in the mucous. It also allows for rapid heat transfer between the capillary net and the air (Taylor, 1974). Beating of cilia propels mucous and allergens, pathogens and toxicants that become entrapped in the mucous towards the glottis, from where it is shunted to the digestive tract by swallowing (Dungworth, 1993). Effective mucociliary clearance depends on coordinated secretions by the goblet cells, sub-mucous glands and serous secretory cells to form an upper mucous layer underlying a more aqueous layer, which allows the upper mucous layer to be transported by cilia (Corcoran, 2010). Non-ciliated (Clara) epithelial cells have P-450 monooxygenase systems that can metabolize xenobiotics, and they can produce inflammatory compounds such as prostaglandins. The mucociliary clearance pathway can adapt to changing environmental conditions, and forms a line of defense against a variety of airborne insults.

Upper conducting airways (bronchi, progressively smaller generations of bronchioles and terminal bronchioles) are lined with pseudo-stratified columnar epithelial cells with a few goblet cells interspersed. Their support tissue contains fibrous connective tissue and cartilaginous plates (Dungworth, 1993). Animals adapted for strenuous physical activity have larger diameter airways to accommodate additional airflow. As bronchioles become progressively smaller, resistance to airflow increases. In these small conducting airways, diseases reflecting altered airflow resistance are said to be diseases of small airways or small airway resistance. As the airways narrow, the epithelium changes from pseudo-stratified ciliated columnar cells with goblet cells to simple columnar epithelium, reflecting the form, function and stresses of these smaller airways. The smallest bronchioles may collapse near the end of expiration, unless there is sufficient collateral circulation to keep them open.

Upper airways (bronchi and bronchioles) have bronchial associated lymphoid tissue; this tissue is similar to gut-associated lymphoid tissue (Dungworth, 1993). Bronchial associated lymphoid tissue is responsible for local immunity in the lung.

### Toxic diseases of the nasal passages

Epistaxis is a typical clinical effect associated with anti-coagulant pesticide toxicosis in animals (Berny, 2007). High doses of ethylene glycol (>10mg/kg) have produced bovine epistaxis and hemoglobinuria (Crowell *et al.*, 1979). The likelihood of equine exercise-induced pulmonary hemorrhage is increased by airborne reactive oxygen substances (ROS), which can destroy the capillary barrier and reduce vasoactive nitric oxides (Manohar *et al.*, 1993; Mills and Higgins, 1997). Rattle snake envenomation is another toxic cause of epistaxis in

horses (Dickinson *et al.*, 1996). These horses have fever, tachycardia, cardiac arrhythmia, thrombosis and hemorrhage. Since horses are often bitten on the nose and are obligate nose breathers, the nostril may swell and must be kept patent.

### Toxic diseases of the conducting airways

Allergic rhinitis that clinically resembles hay fever in humans can occur in horses, cats and dogs (Dungworth, 1993). Nasal granuloma is a chronic form of allergic rhinitis, characterized by degranulation of mast cells and infiltration by eosinophils. Horses with chronic obstructive pulmonary disease have high transpulmonary pressures (Ammann *et al.*, 1998). Constant exposure to dust through litter use or upper respiratory tract infections were blamed as likely causes of feline upper airway inflammation. However, only certain cats become clinically ill, suggesting varying degrees of hypersensitivity to stimulating antigens in cat populations (Dye *et al.*, 1992). Cattle, especially the channel island breeds, and occasionally sheep have a seasonal allergy that resembles this condition. Cattle are believed to be allergic to pollen antigens. Histologically, the epithelium is hyperplastic, eroded and/or infiltrated with eosinophils.

A canine model of nasal congestion and allergic rhinitis has been described (Tiniakov *et al.*, 2003). A very high prevalence of inflammatory gastrointestinal tract problems in brachycephalic dogs that presented with upper respiratory problems was observed clinically, endoscopically and histologically. Some histologically observed inflammatory lesions were not macroscopically visible at endoscopy. Respiratory and digestive signs correlated closely in French bulldog males and heavy brachycephalic dogs (Poncet *et al.*, 2005). It is thought that systemic inflammatory disease can lead to secondary pulmonary infiltration and inflammation (Benedice *et al.*, 2003).

Moderate smoke inhalation injury to the upper airway is usually independent of temperature damage; after as little as 1 hour, endothelin-1 in cells that line the airway increase (Cox *et al.*, 2001). Such changes may contribute to airway inflammation, mucus secretion, pulmonary hypertension, increased airway resistance and decreased lung compliance, in an ovine model of smoke inhalation injury (Cox *et al.*, 2001).

## THE GAS EXCHANGE REGION

### Normal function

Pulmonary parenchyma is divided into units of structure and function called acini (Dungworth, 1993). An acinus

is the gas exchange unit of the lung and of pulmonary parenchyma. The acinus includes all branches of respiratory bronchioles, alveolar ducts and alveoli associated with ventilation; in addition, it contains the vasculature associated with perfusion. Lobules are many acini grouped together and surrounded by connective tissue; in cattle, sheep and horses they form lobules visible at autopsy. In other species lobules are less well outlined. Cells most important to the gas exchange are epithelium (type II and type I epithelial cells). Fibroblasts provide connective tissue and structural support for the alveolus; vascular endothelial cells line the pulmonary capillaries.

### **Ventilation**

Oxygen-rich inhaled air flows through the conducting airways to reach the acini. Oxygen and carbon dioxide are exchanged between capillary blood and air across the alveolar epithelium and vascular endothelium by diffusion along the gas concentration gradient. Carbon dioxide-enriched air is expelled upon expiration. Total lung capacity (TLC) refers to the volume of air in inflated lungs. Some volume of air remains in the lungs following maximum expiration, known as the residual volume (RV). The volume of air moved in and out during breathing is called the tidal volume (TV), while vital capacity (VC) refers to the volume of air moving in and out of the lungs during maximum inhalation and expiration. Oxygen delivery to the blood can be increased by increasing the tidal volume, the respiratory rate or the oxygen concentration in the inspired air. Tidal volume has a fraction in the conducting airways that does not exchange gas, known as the dead volume (West, 2000a). Anatomic dead space refers to the volume of the conducting airways to where oxygen becomes diluted (Fowler's method). Physiologic dead space refers to the portions of the airways that do not contribute to the exchange of carbon dioxide (Bohr's method; West, 2000a). As the breathing pattern becomes shallower and more rapid, the fraction of the non-contributing dead volume in each breath increases. Although we often assume that all regions of the lung are ventilated equally, positional differences are seen in humans. Such differences are minimized when humans are in the supine position. In dogs, the anterior main bronchi receive more ventilation than do the rear ones.

The water solubility of gases influences how deeply they penetrate into the airways and terminal lung structures. Highly water soluble gases, such as SO<sub>2</sub>, do not penetrate deeply. Less water soluble gases, including NO<sub>2</sub>, ozone, CO and H<sub>2</sub>S, penetrate to the deepest lung structures.

Ozone and oxides of nitrogen and sulfur were modeled for absorption throughout the respiratory tract (Tsujino *et al.*, 2005). All three gases had higher

concentration in the airways. For example, ozone was 3–12 times higher at the 5th generation bronchus. Sensitivity analysis indicated that tidal volume, respiratory rate and surface area of the upper and lower airways significantly affected the results. Kinetics of inhaled gaseous substances vary substantially among animals and humans, and such variations are, at least partially, the result of anatomical and physiological differences in their airways.

### **Perfusion**

There are two different types of blood supply to the lung, nutrient vessels that provide nutrition for the lung and pulmonary vessels that specialize in exchanging alveolar oxygen onto the hemoglobin to be carried to the target organs (West, 2000a). The capillaries are just large enough to admit erythrocytes and they are very short. Blood flows around the alveoli as a sheet, and the network of capillaries is said to resemble a miniature underground parking garage.

### **Diffusion**

For some gases for which the blood has a large carrying capacity, such as carbon monoxide, the rate of uptake into the blood is limited by the blood–gas barrier. Thus, the gas exchange is described as diffusion limited. For certain other gases, such as nitrous oxide, which do not bind to or are taken up by the red blood cells, uptake is not limited by diffusion, but by the available blood volume provided by alveolar perfusion. These gases are described as perfusion limited. Oxygen takes the middle road so that its uptake is dependent on the blood–gas barrier characteristics (diffusion limited), as well as the blood volume (perfusion limited). If the alveolar wall becomes abnormally thick, for example when collagen is deposited in the interstitium or with the accumulation of interstitial fluid (edema), the oxygen uptake rate across the barrier is reduced. Alternatively, and more commonly, a failure to match ventilation with perfusion is the cause of poor gas exchange (West, 2000b). If a lung is heavily perfused with minimal ventilation because of a blocked airway, the amount of oxygen that can be exchanged is limited by the mismatch of poor ventilation with good perfusion. Alternatively, gas exchange is compromised if the lung is efficiently ventilated, but receives little or no perfusion. Both conditions are referred to as ventilation–perfusion mismatches.

### **Avian respiration**

There are many morphologic, physiologic and mechanical differences between the avian and mammalian respiratory systems (Brown *et al.*, 1997). In birds, the gas exchange unit is the parabronchus. The parabronchus

has no alveoli. The walls of the narrow passageways called air capillaries serve as the gas exchange surface. Inhaled air reaches the parabronchus via the upper air passageways. Oxygen is extracted as it moves along the air capillaries. After passing through the parabronchus the air is not expelled directly, but moves on to the air sacs. From there the air is moved back through the parabronchus before it is expelled. The parabronchus does not expand and contract like mammalian lungs. Instead, air movement is controlled by expansion and compression of the air sacs. The parabronchus–air sac system provides two opportunities to extract oxygen from inhaled air. In addition, counter flow between blood and air in the parabronchus provides an effective oxygen concentration gradient over a larger fraction of the gas exchange surface area. Partially oxygenated blood comes into close proximity to the air with the highest oxygen concentration, while air with lower oxygen pressure comes into close proximity to blood with the lowest oxygen concentration. Oxygen is extracted about twice as efficiently as in mammals, which is necessary for the increased oxygen demand associated with sustained flight. Air sacs and air membrane spaces provide a reduction in density to birds; reduced density is helpful in staying afloat on water. The increased gas exchange efficiency in birds makes them more susceptible to some inhaled toxicants, such as the fumes released from overheated non-stick cookware coated with polytetrafluoroethylene (Lightfoot and Yeager, 2008). This sensitivity can also be exploited as a very sensitive monitor of air quality. An example of this is the canary in the mine that predicts toxicity to the miners (Brown *et al.*, 1997; West *et al.*, 2006).

## GENERAL PRINCIPLES IN THE PATHOGENESIS OF LUNG DAMAGE CAUSED BY CHEMICALS

### Oxidant burden

Oxidant burden in the lung is frequently associated with airborne pro-oxidants such as nitrogen dioxide, sulfur dioxide, oxidants such as ozone, free radicals, tobacco smoke, or is caused by an overzealous defense by phagocytic cells (Pickrell *et al.*, 1987a; Pickrell and Mageed, 1995; Witschi and Last, 2001). Exposure to oxidants can lead to changes in lung structure and biochemistry (Pickrell *et al.*, 1987b; Witschi and Last, 2001). Pivotal roles have been established for superoxide, pro-oxidant peroxy nitrites, and hydroxyl radicals. Responses depend on the oxidant burden in combination with the glutathione or biological antioxidant concentration. With sufficient oxidant burden and depletion of glutathione, all lung toxins have an inflammatory disease component.

In the presence of significant oxidant burden, but in the presence of high levels of glutathione, lung defensive metabolic enzymes are activated. At intermediate glutathione levels, inflammation is activated using nuclear factor kappa beta. At lower levels of glutathione, mitochondrial enzymes are activated. The relation of programmed cell death (apoptosis) to mitochondrial enzyme activation is being investigated (Nel *et al.*, 2006).

### Toxic inhalant gases

#### Chlorine

Exposure to chlorine may originate from the manufacture of pulp, paper, plastics and chlorinated chemicals (Witschi and Last, 2001). Chlorine gas is irritating to the upper airways, and can cause hemoptysis, dyspnea, tracheobronchitis or even bronchopneumonia in animals inhaling sufficient concentrations. Peak symptoms are typically reached in 30–90 minutes. Patients only infrequently require more than monitoring and rudimentary support measures. Full recovery from such injuries is likely, but permanent loss of function is possible in cases of exposure to very high levels of chlorine (Winder, 2001). Humans exposed to chlorine may have a decreased vital capacity (limited forced expiratory volume) (Mehta *et al.*, 2005). This limitation is frequently reversible and less than that of seasonal allergic rhinitis (Shusterman *et al.*, 2004).

#### Ammonia

Animals and caretakers are frequently exposed to elevated levels of ammonia (NH<sub>3</sub>) gas in swine confinement facilities (Carson, 2004). At greater than 100 ppm, ammonia irritates eyes and respiratory membranes, increases the incidence and intensity of microbial or parasitic infections, and reduces growth rate. High levels of ammonia found in poultry houses have about the same level of toxicity to birds as they would to other animals (Brown *et al.*, 1997). Ammonia concentrations greater than 60 ppm cause kerato-conjunctivitis in broilers; reduced bacterial clearance and enhanced sensitivities to bacterial infections (Carson, 2004).

#### Anhydrous ammonia

Anhydrous ammonia (NH<sub>3</sub>) is injected from pressurized tanks into the ground as a fertilizer nitrogen source. It can be lethal to animals and humans if pressurized tanks are breached or large containers are spilled in transit (Carson, 2004). Anhydrous ammonia reacts with air moisture to form a vapor cloud which can either remain for several hours or disperse efficiently, depending on wind velocity and humidity. In animals and man, the eyes and upper respiratory tract are prime targets. If the air ammonia concentration is higher than 5000 ppm, it

can cause a fatal apnea or laryngeal edema. Survivors may be blinded by corneal lesions and sloughed epithelium. Removal of animals is important if the vapor cloud does not disperse rapidly. Supportive therapy may be curative in moderate exposures. In humans, loss of olfactory ability was associated with exposure to anhydrous ammonia, as well as a history of wheezing and asthma, and of flu-like illness (Snyder *et al.*, 2003).

### Carbon dioxide

Carbon dioxide (CO<sub>2</sub>) is well tolerated, even at concentrations as high as 5%. Higher concentrations stimulate the rate and depth of respiration (Carson, 2004). It is, however, being explored as a novel human stressor (Kaye *et al.*, 2004). It is an asphyxiant at extremely high concentrations (>40%). Because it is heavier than air, it collects in the lower portion of animal facilities (Carson, 2004). It is used as a euthanasia agent in some laboratory animal species.

### Carbon monoxide

Carbon monoxide (CO) is a product of incomplete combustion of hydrocarbon fuels. It has background levels of about 0.02 ppm in rural areas, 13 ppm in urban areas and 40 ppm in areas of high urban traffic. Improperly vented or adjusted heaters, and fires, especially those burning more coolly, are frequent sources of increased CO.

Carbon monoxide binds about 250 times as tightly to hemoglobin as oxygen, forming carboxyhemoglobin (COHb). Oxygen is displaced by CO, limiting the ability to take up oxygen and give off carbon dioxide in the lungs. Because of their high respiratory exchange efficiency, birds are unusually sensitive to carbon monoxide (Brown *et al.*, 1997). They often require relatively more oxygen per unit body weight because they have smaller body sizes and more active metabolisms.

Measurement of COHb is diagnostic of CO intoxication (Carson, 2004). In humans, <3% COHb is considered normal; 6–8% causes drifting of attention; 10–20% headaches; 20–30% dizziness; 30–60% tachypnea, tachycardia and confusion; and 60% fatality. Birds respond more acutely than mammals, and canaries have been used as sentinels for miners (Brown *et al.*, 1997; Carson, 2004). Treatment requires, at a minimum, fresh circulating air; 100% oxygen may be lifesaving. Prognosis depends on the amount of COHb and the hypoxic brain damage. Pulmonary function should be monitored for at least 2 weeks, and in some cases 6 weeks.

### Methane

Methane (CH<sub>4</sub>) becomes an asphyxiant at >85%; it is an explosion hazard at 10–15%. It is substantially lighter than air and will flow above water in a swamp (Carson, 2004).

### Hydrogen sulfide

Since hydrogen sulfide (H<sub>2</sub>S) is insoluble in water, it may expose the deepest recesses of the lung. At 50–150 ppm level H<sub>2</sub>S causes pulmonary edema (Carson, 2004). *In vitro*, H<sub>2</sub>S induces apoptosis of aorta smooth muscle cells, regulated by mitogen-activated protein kinase (ERK MAPK) that activates caspase-3 (Yang *et al.*, 2004). H<sub>2</sub>S is less toxic to birds than to other animals; 2000–3000 ppm will change respiratory rate and depth, while 4000 ppm will kill them in about 15 minutes. The mechanism may relate to the greater gas exchange efficiency of parabronchi (Brown *et al.*, 1997).

Hydrogen sulfide's ability to paralyze the respiratory tract is its greatest danger to animals and humans (Carson, 2004). Above 500–2000 ppm, mammals are said to take the second, but not the third, breath. Above 500 ppm, H<sub>2</sub>S begins to cause permanent neurologic damage. Data from rats trained to run a reversed contingency maze suggested that H<sub>2</sub>S may impair learning by increasing the animals' susceptibility to interference from irrelevant stimuli (Partlo, 2001).

Hydrogen sulfide is readily detectable as a rotten egg smell. Humans and presumably animals can detect hydrogen sulfide at 0.025 ppm (Carson, 2004). Above 200 ppm, however, hydrogen sulfide paralyzes the olfactory apparatus so it may not be detectable by smell. Higher concentrations seem to paralyze smell more rapidly. Thus, animals or humans may have only a very brief instant to smell hydrogen sulfide at high concentrations; it is dangerous to ignore the smell because its duration can be so brief.

Hydrogen sulfide is heavier than air and insoluble in the water of manure pits (Carson, 2004). Thus it can exist as bubbles in swine manure pits inside hog houses, ready to be released and expose animals and workers on agitation. Taking appropriate steps to protect rescuers, exposed people or animals not breathing should be dragged outside. If breathing is not re-established spontaneously, artificial respiration should be applied until spontaneous respiration returns.

### Nitrogen dioxide and ozone

Nitrogen dioxide (NO<sub>2</sub>) is considered with ozone (O<sub>3</sub>), because NO<sub>2</sub> is a pro-oxidant and O<sub>3</sub> an oxidant. In agriculture, NO<sub>2</sub> can come from silage or relatively airtight silos, where it is usually found towards the top (Carson, 2004). Indoor air NO<sub>2</sub> and O<sub>3</sub> can come from second-hand cigarette smoke. Nitrogen dioxide exposure from newly opened silage bags may modestly affect hungry cattle if exposure levels are unusually high (i.e., in large confined animal feeding operations dairies), but usually they are more likely to affect caretakers in upright silos. Nitrogen dioxide has low water solubility, and can pass through the upper airway and permanently damage pulmonary parenchyma where residence times are

longer. At ambient NO<sub>2</sub> (2–3 ppm) there is little damage or clinical signs. At higher levels, for example 20 ppm, it induces lung edema. Animals develop coughing, some fluid in the lungs, death of type I epithelial cells, coalescing alveoli and an increased collagen production, but no morphologic evidence of fibrosis (Gregory *et al.*, 1983; Pickrell *et al.*, 1987a; Mauderly *et al.*, 1987; Carson, 2004). Animals that die at varying times after exposure have evidence of pulmonary edema and emphysema.

Birds are unusually sensitive to NO<sub>2</sub> and O<sub>3</sub>, depending on exposure level. Caged pet birds may be sensitive to second-hand cigarette smoke, especially in the presence of heating/combustion sources. Newly hatched chicks die after 5 days' exposure to 1–4 ppm O<sub>3</sub>; exposure to 0.3–0.7 ppm O<sub>3</sub> causes pulmonary hemorrhage in these chicks (Brown *et al.*, 1997). Pulmonary hemorrhage in mammals is typical of acute high-level oxidant exposure of a somewhat more intense nature than that associated with pulmonary edema (Pickrell *et al.*, 1987a).

## Particle size and clearance

### Particle size and deposition mechanisms

Inhaled aerosol particles are frequently of multiple sizes (polydispersed). Particles of different aerodynamic sizes deposit in different anatomic areas of the mammalian and avian respiratory tracts. In mammalian lungs, particles with aerodynamic diameters of 5–30 micrometers mostly deposit by inertial impaction in the nasopharyngeal region because they do not follow curving airflow well (Witschi and Last, 2001). Inertial impaction in bird respiratory tracts is influenced by flow velocity and Reynolds numbers (Re) (trachea 100 cm/sec at Re = 700; primary bronchi 130 cm/sec and Re = 600; narrowed primary bronchus 200 cm/sec and Re = 550). The expected sites of inertial impaction in birds are similar to those in mammals (Brown *et al.*, 1997).

Slightly smaller particles (1–5 micrometers in aerodynamic diameter) mostly deposit by gravitational sedimentation in the conducting airways – the trachea, bronchi and bronchioles – as airflow speed progressively slows down towards the airway terminals. In the human lung, sedimentation is an important mechanism for deposition at sizes greater than 0.2 micrometers in diameter (Witschi and Last, 2001). In birds, deposition probability is a product of (residence time)(aerodynamic diameter). In parabronchi, where flows are as low as 3 cm/sec (Re = 2), and residence times may be up to 1 min for complete change of air sac volume at rest, deposition probabilities can be quite high (Brown *et al.*, 1997).

Particles <1 micrometer in aerodynamic diameter have a good probability to deposit by Brownian diffusion when their random movement causes them

to bump into wet surfaces (Witschi and Last, 2001). Diffusion, like sedimentation, is most important where residence times are the longest. The probability of deposition by diffusion increases with decreasing particle size, so that deposition of particles with aerodynamic diameters of less than 0.5 micrometers is largely by diffusion. Breathing pattern can be important. During exercise particles acquire higher velocity, momentum and inertia that increase impaction deposition higher up the respiratory tract. Alternatively, breath holding causes more deposition by gravitational sedimentation and diffusion.

### Particle clearance

Particle clearance in mammals is important to defense of the lung. Rapid clearance lessens exposure time and extent of injury. Clearance of intact particles depends heavily on pulmonary alveolar macrophages and the mucociliary escalator. Alveolar macrophages phagocytose particles, then migrate to the bronchi and trachea for clearance. Ultrafine particles that enter the alveolar interstitium may be cleared at a much slower rate (Shinohara *et al.*, 2010). Particles can leave the lung and enter the vascular system, causing a risk to organs downstream from the lung (Nemmar *et al.*, 2001; Borm *et al.*, 2006). Alternatively particles may be soluble in aqueous media and can be dissolved in mucus. Fine and ultrafine (nano) particles with much of their mass in contact with the surface are especially subject to such dissolution. Factors affecting this solubility are quite complex; they include but are not limited to composition of the aqueous fluid, particle size, particle chemical composition, steepness of concentration gradient, curvature, agglomeration and aspect ratio (Nemmar *et al.*, 2001; Borm *et al.*, 2006). Some ultrafine particles that are deposited in the nasal mucosa can be transported to the brain via the olfactory bulb (Oberdörster *et al.*, 2004).

Particle solubility and chemical reactivity are influenced by the physical–chemical environment. Bicarbonate in lung simulant fluid, for example, can enhance solubility in particles moderately soluble in aqueous media. To obtain relevant data solubility and reactivity should be measured in an environment as near to that of the lung environment as possible. This can sometimes be accomplished with *in vitro* conditions closely simulating biological solutions (Powers *et al.*, 2006). Solubility is thought to be a function of chemical activity, specific surface area, radius and curvature, agglomeration and specific chemicals that are adsorbed to the NSP (Borm *et al.*, 2006). It is important to consider not just solubility in water, but in fluids that bear significant resemblance to that of the epithelial lining fluid (ELF). Epithelial lining fluid is the fluid that lines the epithelial cells in the respiratory tract.

A volume of 40–100 ml is predicted for mature humans. The pH varies from 6.9 at the end of inspiration to 7.5 at the end of expiration. Bicarbonate is a major buffer, and the pH variation is caused by varying CO<sub>2</sub> during expiration (Langmuir, 1965). Bicarbonate in lung simulant fluid increases the solubility of magnesium oxide (MgO) (Pickrell *et al.*, 2006). Stoichiometry of the likely chemical species suggests a conversion of MgO to magnesium hydroxide (Mg(OH)<sub>2</sub>) in aqueous media, and a subsequent conversion to the hydrated carbonate nesquehonite.

In chickens, small dust particles were found trapped in the respiratory epithelial cell trilaminar surfactant (Brown *et al.*, 1997). No particles were found in the vascular system, kidneys and heart, suggesting that at least those particles did not enter the vascular system. After 1 hour 54% of the particles remained, while after 36 hours approximately 36% remained, suggesting that appreciable clearance took place. The mechanism of the clearance is not completely clear. However, parenchymal respiratory epithelial cells could have transported particles toward the pulmonary interstitium. Particles in the mammalian lung too small to be efficiently phagocytized were also transported into the lung's interstitium. In bird lungs, there was a virtual absence of phagocytes; the absence may have caused the epithelial cells to take on a larger role. Following experimental introduction of Sephadex or Freund's adjuvant, phagocytes with physiological features similar to macrophages can enter the bird's pulmonary spaces.

Birds living in dusty environments – kiwis near the desert with abundant sand and poly dispersed loose dust, or birds living near or flying over volcanic ash – show significant pathology and signs after only short exposures to small dust particles. Confined animal feeding operations with poultry raised in high population densities often show reduced production and pathology at necropsy (Brown *et al.*, 1997).

## LUNG TO INJURY

### Acute responses to lung injury

#### Airway reactivity

Mammalian large conducting airways are surrounded by bronchial smooth musculature (BSM) (Witschi and Last, 2001). The muscle tone is modulated by the autonomic nervous system. Reflex contraction occurs after stimulation by irritants. Bronchoconstriction can also be provoked by cholinergic drugs. This stimulation is used in diagnosis as a basis to assess the "twitchiness" of BSM – at how low a level the bronchi can be induced to constrict.

These agents bind to receptors and trigger increased intracellular cyclic monophosphates – adenosine and guanosine, respectively (cAMP and cGMP). Histamine, prostaglandins, nitric oxide and leukotrienes also influence bronchoconstriction.

#### Pulmonary edema

Pulmonary edema is exudative, and it indicates acute lung injury (Witschi and Last, 2001). Edema is associated with leakage or interruption, as well as thickening of the alveolar capillary membrane. Edema fluid creates a thicker diffusion barrier, and contributes to a mismatch of ventilation to perfusion. The mismatch limits the rate of oxygen exchange from the air of the alveoli to the blood of the alveolar capillaries, even if the alveolar capillary unit is normal in all other respects. Frequently, very intense pulmonary edema will include some evidence of small pinpoint pulmonary hemorrhage. Even brief edema may damage or denude epithelium, or endothelium, or both.

Heart failure is often associated with cardiogenic lung edema, as demonstrated by a case of fatal *Taxus* (Japanese yew) poisoning in horses with pulmonary congestion, hemorrhage and edema (Cope *et al.*, 2004), as well as calves given *Nerium oleander* (Oleander) clippings, which developed tachycardia and pulmonary edema (Galey *et al.*, 1996). Very high levels of fumonisin (>100 ppm in diet) may cause fatal pulmonary edema in pigs 1–4 hours after exposure (Marasas, 2001). Non-cardiogenic pulmonary edema has been associated with airway obstruction, cranial trauma, seizures or electric shock (Drobatz *et al.*, 1995). In horses, hyperhydration prior to exercise may be detrimental to respiratory function due to some degree of edema (Sosa *et al.*, 2002). Laboratory rodents receiving very high doses of paraquat may die with pulmonary edema and hemorrhage (Witschi and Last, 2001).

Some toxic agents, such as alloxan, which denude the alveolar capillary unit, reduce the likelihood of recovery (Witschi and Last, 2001), and may lead to significant collagen deposition (Pickrell and Villegas, research communication). If the changes are intense and architecture is severely compromised, pulmonary fibrosis may result. From some insults (histamine) an uneventful recovery may result. Several other insults (e.g., paraquat) cause sufficient injury to lead to healing by secondary intent (fibrosis).

We determine the extent of pulmonary edema by relating lung wet weight to body weight (Witschi and Last, 2001). Alternatively, lungs, lobes or slices can be weighed before and after drying. The accuracy of the second procedure is limited by the uniformity of the edema, but again this may be a useful indicator (Witschi and Last, 2001).

Acute respiratory distress, particularly acute pulmonary edema, is treated with diuretics such as furosemide, intranasal oxygen, bronchodilators, corticosteroids and alleviation of the underlying cause (Foreman, 1999). It is especially important to address the underlying cause in many of these conditions. Furosemide was formerly used in North America as a race-day preventive for exercise-induced pulmonary hemorrhage. The difficulty with using furosemide as a preventive is that furosemide may also be a performance-enhancing agent.

#### *Nasal and upper airway reactivity*

Upper airway irritant gases and particulates, especially ultra-fine particulates with greatly increased surface area, stimulate nasal (trigeminal) nerve endings (Witschi and Last, 2001). They also elicit avoidance reactions. Phosphine (PH<sub>3</sub>), for example, is liberated after ingesting zinc phosphide rodenticide; PH<sub>3</sub> irritates nasal and upper airway nerve endings resulting in avoidance reactions such as breath holding and subsequent paroxysmal breathing (Knight, 2006). Other agents, such as HCl, NH<sub>3</sub>, NO<sub>2</sub> and COCl<sub>2</sub>, appear to initiate serum leakage through toxic effects on epithelial cells or endothelial cells or both. Highly reactive molecules cause their reactions in a different manner. It is unlikely that ozone can penetrate fluid layers to cause direct toxicity; it is more likely that reactive molecules initiate a cascade of reactive oxygen substances such as aldehydes and hydroperoxides.

The lung contains most of the metabolizing P450 isoenzymes found in other tissues, but often at lower concentrations than in the rest of the body. These P450 isoenzymes are highly inducible. Activation of the enzymes is an initial defensive reaction which may contribute to healing and protecting the lung (Nel *et al.*, 2006). Although the P450 isoenzymes are clearly activated after exposure, it is not clear whether the response is sufficiently linear and consistent to use them as a biomarker of exposure. Other metabolizing enzymes in the lung include glutathione-S-transferase and glutathione peroxidase. In fact, the lung has been found to contain several forms of glutathione-S-transferase.

#### *Mediators of lung toxicosis*

Cytokines (tumor necrosis factor alpha (TNF $\alpha$ ), transforming growth factor  $\beta$  (TGF- $\beta$ ) and interleukin 1B (IL-1B)) are found in respiratory tract lavage fluid, and are associated with cultured whole lung tissue and of specific lung cells (lung epithelial cells and fibroblasts) (Witschi and Last, 2001). Cytokines can be used in studies to signal toxicant-induced lung damage. TNF $\alpha$  and IL-1B, for example, signal acute lung injury. TGF- $\beta$  and the cytokines signaling acute lung injury are part of the pathogenesis of pulmonary fibrosis. IL-1, IL-2, IL-5 and

IL-8 are thought to be essential components of epithelial lung cell injury. Finally, IL-4, IL-5 and IL-13 are thought to be associated with allergenic responses.

#### *Cell proliferation*

Toxicants can cause either reversible or irreversible lung changes (Witschi and Last, 2001). Toxic changes that cause major alterations in lung architecture usually cause irreversible lung injury. Severe tissue injury is followed by either tissue loss (emphysema) or healing by secondary intent (fibrosis). Although information about the typical responses associated with specific toxicants is available, it is still unclear how different responses are triggered.

When type I lung epithelial cells are injured and die following exposure to an oxidant gas, some type II lung epithelial cells proliferate, and begin to flatten and stretch to cover the denuded area. Clara cells proliferate following type II proliferation (Witschi and Last, 2001). Migration of blood monocytes to injured areas may trigger responses from other cells in the parenchymal lung unit, for example interstitial fibroblasts, myofibroblasts and endothelial cells. If the damage is relatively minor, the lung may heal with a relatively normal appearance, a higher total lung collagen content and minimal, if any, alteration of pulmonary function.

### **Chronic responses of the lung to injury**

#### *Fibrosis*

Healing by secondary intent, often called pulmonary fibrosis, may be either reversible or irreversible depending on the degree of injury. When lung injury is too severe, or persists too long to heal spontaneously, for example with high levels of paraquat, fibroblasts will attempt to fill the void left by type I lung epithelial cell death. Fibroblast proliferation may contribute to ventilation perfusion mismatch, making the lung less functional than when repaired by epithelial proliferation. In addition, there would be greater alteration of pulmonary architecture and increased numbers of interstitial fibroblasts. Increased fibroblasts making normal amounts of collagen would be expected to collectively make more collagen. If minimal to moderate alterations in pulmonary architecture are present the lung will spontaneously revert back to normal (Pickrell *et al.*, 1983). If greater alterations have been made to pulmonary architecture, the interstitial fibrosis may become irreversible and form dense fibrous scars (Pickrell *et al.*, 1983; Witschi and Last, 2001).

There are over 10 genetically distinct collagen types in animals and humans. Types I and III are major interstitial collagens in the lung. Type III collagen is more compliant

than type I. An increase in type I relative to type III collagen, which has been shown in experimental models of fibrosis caused by paraquat and asbestos, makes the lung even stiffer than if only an increased amount of collagen was present and the ratios of type I to type III collagen were unchanged (Witschi and Last, 2001).

### Emphysema

Emphysema has been defined as enlarged air spaces due to tissue destruction without fibrosis (Witschi and Last, 2001). The lungs become larger, more compliant and hyperinflated. Loss of gas exchange surfaces causes a reduction in gas exchange potential. Alveoli collapse, air spaces become distended and irregular, and air may become trapped. This makes it more difficult to expel air accumulated in distended alveoli. Patients become emaciated, have increasingly forced expirations and develop heave lines due to increasingly difficult and forceful expirations (Lowell, 1990).

Fibrosis is associated with local, heterogenic, compensatory emphysema. In areas where damage is sufficiently low, the lung heals normally. In areas where injury is more extensive, fibroblast proliferation and the excess production of collagen may result in fibrosis. In a still higher level of injury, even fibroblasts cannot effectively fill voids, healing by secondary intent fails and lung tissue is lost and emphysema forms. The extent to which this varied may be related to variations in local dose, the reserve of biological antioxidants or the balance between proteinase–antiproteinase (Pickrell *et al.*, 1983, 1987a, b).

### Asthma

In asthma, small conducting airways constrict at lower irritant concentrations than in normal lungs. Bronchoconstriction reduces airway diameter resulting in increased small airway airflow resistance. Symptoms include coughing, wheezing and progressive dyspnea (Witschi and Last, 2001).

Guinea pigs are highly sensitive to upper airway irritation and to subsequent development of bronchial asthma. Other animals that develop syndromes similar to human asthma include horses, dogs and cats (Padrid, 2000; Davis and Rush, 2002; McCue *et al.*, 2003; Pirie *et al.*, 2003; Reinero *et al.*, 2006). In horses, an asthmatic condition known as heaves is associated with inhaled endotoxins and organic dust particulates, which are thought to be synergistic in their effects (Pirie *et al.*, 2003). Potentially detrimental effects can be reduced by maintaining horses in “low dust” stables or at pasture, since these environments have significantly lower airborne dust and endotoxin levels (McGorum *et al.*, 1998). Poultry farmers have significantly higher incidences of chronic bronchitis. The major risk factor for respiratory symptoms was shown to be inadequate ventilation of

animal houses (Radon *et al.*, 2002). Airborne endotoxin can cause flu like symptoms in birds; this condition must be differentiated from infectious avian influenza (Joseph and Subbarao, 2005).

Specific allergen immunotherapy is a potential therapy for feline asthma. In one study, Rush Immunotherapy (RIT) blunted eosinophilic airway inflammation in experimental feline asthma. BAL cytokine profiles favoring a Th2 response developed after giving Bermuda grass antigen. RIT shifted the response to increased IFN- $\gamma$ , and IL-10 thereafter. The mechanism of RIT may involve changes in allergen-specific immunoglobulin production, induction of hyporesponsive lymphocytes or alteration of cytokine profiles (Reinero *et al.*, 2006).

### Lung cancer

In laboratory animals, spontaneously occurring malignant pulmonary tumors are rare, except for very old animals. If lung tumors do develop in laboratory rodents, they are generally peripheral adenomas instead of the more central tumors seen in humans. Adenomas usually originate from type II pulmonary epithelial cells, or Clara cells. These adenomas rarely have sufficient time to develop into carcinomas. Occasionally, lung tissue injury causes bronchogenic adenocarcinoma, which is an unusual lung tumor in cats; it may metastasize to the digits and to the abdominal wall. Average survival time for tumors metastasizing to the digits is only ~5 weeks (Van der Linde-Sippman, 2000; Petterino *et al.*, 2005).

Certain mouse strains (strain A and Swiss-Webster mice) with mutations in the K-ras genes similar to human carcinomas develop adenomas that increase in incidence after the inhalation of certain toxicants or carcinogens. These mice are potential models for human lung carcinogenesis (Witschi and Last, 2001).

Rat lungs occasionally contain lesions of epithelial cells surrounding material identified as keratin (Witschi and Last, 2001). The cells may compress lung parenchyma and occasionally invade it. These lesions are found more frequently in long-term tests of animals exposed to substances not considered to be carcinogens such as carbon black, titanium dioxide and certain man-made fibers. Controversy exists as to whether these are cysts filled with keratin, or can be classified as tumors.

In humans, it has been estimated that 80–90% of all lung tumors are caused by inhaling cigarette smoke (Witschi and Last, 2001). Dogs are companion animals that live with their owners over long periods of time. Although rare, some dogs developed either nasal or lung tumors after being exposed to owner's second-hand cigarette smoke. In described cases, the tumors were carcinomas – epithelial in origin and malignant. Dogs living for protracted periods of time in a home

with a smoker were more susceptible to lung cancer than those in homes of non-smokers (odds ratio = 1.6, 95% confidence interval 0.7–3.7). No relations were found between cancer rates and increasing the number of packs of cigarettes smoked per day or the proportion of time the dog spent within the home. However, dog breeds with short and medium length noses had an increased tendency to develop lung cancer (odds ratio = 2.4, 95% confidence interval 0.7–7.8). Dogs with long noses (dolicephalic breeds) tend to deposit carcinogenic particles in the nasal cavity, and may develop nasal carcinomas. Alternatively dogs with shorter noses (brachycephalic breeds) tend to allow carcinogenic particles to deposit in the upper airways and develop bronchogenic carcinomas (Reif *et al.*, 1992). The most frequent tumors in dog lungs, however, are mammary tumors that metastasize to the lung.

## Agents known to produce lung injury in animals

### Zinc phosphide

Poultry are highly susceptible to zinc phosphide poisoning. For example, approximately 200 chickens inadvertently given zinc phosphide were found dead with no clinical signs after the flooring of a slat-and-litter house was breached (Tiwary *et al.*, 2005). Gross necropsy revealed intense congestion of the viscera; histopathologic examination revealed severe pulmonary edema and congestion of the chickens' lungs, hearts, livers and kidneys (Tiwary *et al.*, 2005).

### Smoke

Smoke inhalation injury is common in animals when confinement does not allow them to move away from smoke-filled air. Cardiac dysfunction in sheep following combined burn and smoke injury was mostly related to hypovolemia, and was improved by aggressive fluid therapy. However, later myocardial contractile dysfunction seemed to be correlated with smoke inhalation injury (Soejima *et al.*, 2001). In chickens, the interparabronchial septal spaces were measurably thickened and engorged as a result of hydrostatic pulmonary edema, similar to the effect of hydrostatic pulmonary edema in mammals (Weidner *et al.*, 2002). Under similar conditions, air sacs thickened, and microvilli had increased density (Weidner, 2000).

### Overheated frying pans

Exposure of caged birds to gases released from overheated non-stick cookware has been shown to result in a high percentage of deaths (Brown *et al.*, 1997). Most of

these birds have pulmonary edema and hemorrhages. Proximity to the source is an important risk factor. Birds in adjacent rooms may have only minimal pulmonary reactions compared to birds close to the source, even when the total exposure is similar for both (Brown *et al.*, 1997). The mechanisms of these differences are not known at this time. It has been suggested that physical-chemical changes occur in released substances over time, making them less toxic. Alternatively, particles released from overheated surfaces in the same room are smaller in diameter, and more numerous, closer to the source, whereas those further away tend to coalesce into larger particles. Thus, birds in the same room would be exposed to more surface areas per unit mass than those in adjacent rooms.

### Tryptophan and *Perilla frutescens*

Tryptophan toxicity is associated with cattle consuming tryptophan in lush green forages (Pickrell and Oehme, 2004). The rumen converts tryptophan to 3-methyl indole (MI), which is metabolically activated by cytochrome P450 to a reactive compound in the lung. In a similar toxicosis, perilla ketone and 4-ipomeanol from *Perilla frutescens* (beef steak plant) damage endothelial cells and type I pulmonary epithelium (Nicholson, 2004; Pickrell and Oehme, 2004).

At high doses, MI leads to pulmonary edema, excess proteolysis, tissue destruction, emphysema and death within 6–24 hours after the onset of clinical signs (Pickrell and Oehme, 2004). Several pounds of green forage containing 4-ipomeanol may be fatal to a cow within 1–2 days (Nicholson, 2004). At lower exposure levels, animals may have respiratory signs (depression, respiratory grunt, wheeze and froth flowing out of the nostrils), but will recover over 24–72 hours. These animals will recover in 24–72 hours with minimal to no physiological impairment. However, proliferation of type II alveolar cells may persist with no demonstrable physiological consequences. If exercised, cattle with intermediate signs can be pushed into the acute syndrome; they will worsen rapidly, develop significant lung edema and may die (Pickrell and Oehme, 2004).

# Cardiovascular toxicity

Csaba K. Zoltani

## INTRODUCTION

Cardiotoxicity is a dysfunction of the electrophysiology of the heart. Primarily this manifests itself in inadequate oxygenation of the blood, affecting all organ functions. The electrophysiological dysfunction in animals is primarily caused by phytotoxins, chemical toxicants and venoms.

The ingested poisonous feedstock and environmental toxins may lead to a wide variety of symptoms. In some cases, cardiotoxicity is only ancillary for the initial diagnosis but its recognition and subsequent treatment may be of primary importance for the outcome.

Cardiotoxicity is evidenced by changes in the electrocardiogram (ECG). Initial indicators of cardiac injury include increases in the amplitude of the T-wave and ST-segment. In addition, biomarkers of cardiac toxicity give insight into the nature of the injury. These include the levels in the serum of the two isoforms of cardiac troponin I and T, whose levels rise after ischemia and indicate myocardial necrosis. Also myoglobin, which is released by injured myocardial cells, is present. Levels of creatine kinase (CK), particularly CK-MB, rise after the onset of infarction or even after tachycardia, and are indicative of cardiac muscle damage. Lactic dehydrogenase (LDH), which catalyzes the conversion of lactate↔pyruvate, is present in many tissues with variable activities of its five isoenzymes activities (LDH-1→LDH-5). LDH-1 isoenzyme is found primarily in heart tissue, while LDH-2, LDH-3, LDH-4 and

LDH-5 are found in many other tissues. Tissue damage elevates LDH activity. When LDH-1 > LDH-2, this indicates heart attack or cardiac muscle injury. FABP3, an intracellular fatty acid-binding protein and a marker for myocardial damage, is also released into plasma after myocardial injury.

This chapter addresses the primary cardiac problems encountered in animals as a result of unsuitable feedstock, or the introduction of poisons into their system by alternate means.

## PLANT-RELATED CARDIOTOXICITY

The primary cause of cardiotoxicity in animals is the ingestion of toxic plants. Most plants are widely distributed, though possibly geographically contained, and toxicity is dependent on the season, environmental conditions, particular ingredient and part of the plant accessed. Excellent references and databases on plants exist that give detailed information (Kingsbury, 1964; Frohne and Pfander, 2005; Burrows and Tyrrel, 2006; Panter *et al.*, 2007; FDA, 2008). Additional information on plants and their effect on the cardiovascular system is described elsewhere (Beasley, 1999; Knight and Walter, 2001).

Plants can contain a variety of toxic chemicals and the majority of them are either glycosides or alkaloids that produce cardiac toxicity.

## GLYCOSIDE-CONTAINING PLANTS (SEE TABLE 16.1)

### *Digitalis purpurea* (foxglove)

Important cardiac drugs are derived from foxglove, including digitalis that helps to increase the force of contraction of the heart muscle. However, the effect of cardiac glycosides is dose dependent and has a very narrow therapeutic range, i.e., slight overdosage induces toxicity. Glycosides, with a digitalis-like effect, are lethal in domestic animals upon ingestion of 100–200 mg/kg body weight. The main toxic glycosides in foxglove include digitoxin, digitonin and digitalin. The LD<sub>50</sub> of digitoxin in cats is 0.18 mg/kg body weight, and in guinea pigs is 60 mg/kg body weight. Poultry as well as ruminants are also affected (Thomas *et al.*, 1987).

In general, the mechanism of toxicity of digitalis glycosides at the cellular level involves interference with the Na<sup>+</sup>/K<sup>+</sup>-ATPase pump, resulting in decreased intracellular potassium (K<sup>+</sup>) and consequently decreased resting potential. At high doses, glycosides in the heart affect an electrical conduction, resulting in an increased vagal tone to the atrioventricular (AV) and the sinoatrial (SA) nodes. This may culminate in cardiac arrhythmias and asystole (cardiac arrest). Additionally, they cause myocarditis, myocardial lesions and hemorrhage.

Digoxin overdose induces ECG changes, such as ST-depression, T-wave inversion, PR-interval prolongation and QT-interval decrease, thereby leading to the signs of cardiac toxicity. Digoxin interferes with the binding sites of potassium ions of the Na<sup>+</sup>/K<sup>+</sup>-ATPase

pump. This increases the level of Na<sup>+</sup> ions in the myocytes that causes higher intercellular calcium ions resulting in increased cardiac contractions. In addition, cardiac glycosides have vagotonic effects, resulting in bradycardia and cardiac arrest (Beasley, 1999; Liu *et al.*, 2010).

Cardiac symptoms caused by glycosides of *Digitalis purpurea* include strong cardiac contractions, prolonged diastole, pulse and cardiac rhythm abnormalities, hyperkalemia and ventricular tachycardia (Lin *et al.*, 2010).

Treatment for digitalis poisoning is usually symptomatic and involves multi-dose activated charcoal and atropine.

### *Asclepias* spp. (milkweeds)

Milkweed is a perennial plant indigenous to the Great Plains and from North Carolina to Maine (Kingsbury, 1964; Stevens, 2000). The most toxic is labriform milkweed, followed by the western whorled milkweed. Milkweeds exude a milky juice from their broken surfaces. Most milkweeds contain a mixture of steroidal glycosidic cardenolides that are toxic to animals (Panter *et al.*, 2007). The cardenolides induce cardiotoxicity by inhibiting Na<sup>+</sup>/K<sup>+</sup>-ATPase activity.

Horses, cattle, sheep, goats and poultry are all susceptible, with a dosage of whorled milkweed of 0.1–0.5% body weight of the animal being fatal. Clinical signs appear within few hours of plant ingestion. Cardiac signs include bradycardia or tachycardia, hypotension and arrhythmia. Death occurs within a few days of plant exposure. Histological lesions and myocarditis are

TABLE 16.1 Glycoside-containing plants

Botanical name	Common designation	Cardiac symptoms	Ancillary cardiac effect	Toxicity
<i>Asclepias</i> spp.	Milkweed	weak, rapid pulse, arrhythmia	hypotension, arrhythmia	dosage of 0.5% b.w. fatal for horses, cattle
<i>Persea Americana</i>	Avocado	heart failure, cardiomyopathy	necrosis of myocardial tissue, inflammation of the heart; horses, rabbits, goats, ostriches affected	sheep fed 2.5 g/kg b.w. for 32 days developed cardiac insufficiency
<i>Digitalis purpurea</i>	Foxglove	cardiac rhythm abnormality, hyperkalemia	stronger cardiac contractions and slower contractions through stimulation of the vagus, prolonging diastole; affects cats, dogs, livestock	LD <sub>50</sub> (cats) 0.18 mg/kg b.w., guinea pigs 60 mg/kg b.w.
<i>Nerium</i> spp.	Oleander	bradycardia and/or tachycardia, ventricular fibrillation	in sheep depression of ST on ECG, hyperkalemia, serum potassium may increase two-fold, 2nd degree AV block	LD <sub>50</sub> (goats) 330 mg/kg, b.w., in sheep 110 mg/kg b.w.
<i>Convallaria majalis</i>	Lily of the valley	sinus tachycardia, heartblock	cardiac signs may be delayed, heart becomes hyperirritable	LD <sub>50</sub> (cat) 0.14 mg/kg b.w.
<i>Rhododendron</i> spp.	Azalea, rhododendron	arrhythmia, hypotension, weak heart rate	contains the toxin grayanotoxin	LD <sub>50</sub> (mice) 5.1 mg/kg b.w.
<i>Kalmia</i> spp.	Laurel	bradycardia	excitable cells remain depolarized	LD <sub>50</sub> (rats) 2–5 mg/kg b.w.

common (Clark, 1979). Treatment includes lavage with activated charcoal and a cathartic.

### *Persea americana* (avocado)

*Persea americana* of the family *Lauraceae* is a tree found in Mexico and commercially grown in the United States (mainly in California and Florida). The leaves, fruit and seeds of the plant are considered to be toxic, with the leaves being the most toxic. A variety of animal species have been naturally or experimentally intoxicated by *P. americana* including cattle, goats, horses, rats, mice, rabbits, sheep, ostriches, dogs and pet birds. The toxic principle is persin, which causes myocardial necrosis in birds and mammals. Persin also targets mammary glands in lactating animals. Sheep fed 2.5g/kg body weight for 32 days developed cardiac insufficiency. Upon ingestion of avocado, dogs also develop myocardial damage. At high doses, exceeding 100mg/kg body weight, the myocardium is affected with necrosis of myocardial fibers (Oelrichs *et al.*, 1995). Goats fed fresh avocado showed cardiac distress (Grant *et al.*, 1991). Recently, Poppenga *et al.* (2010) reported acute avocado poisoning in goats. Gross and microscopic findings included pulmonary congestion, and multifocal, necrotizing, neutrophilic myocarditis. Treatment is symptomatic and nonspecific.

### *Nerium* spp. (oleander)

*Nerium oleander* (oleander) is an evergreen shrub of the *Apocynaceae* family that thrives principally in subtropical regions. All oleanders contain cardenolides that exert positive inotropic effect on cardiac muscle. Their action is derived from inhibition of the plasmalemma (cell membrane)  $\text{Na}^+/\text{K}^+$ -ATPase.

In sheep, a dose of 110mg/kg body weight led to death preceded by decreased heart rate, tachyarrhythmia and conduction defects affecting sinus node, the AV node and elevated CK (Eddleston *et al.*, 2000). ECG revealed bradycardia, AV block, depression of the ST segment, tachycardia and ventricular fibrillation (Aslani *et al.*, 2004). Histopathological examination revealed myocardial degeneration. In goats, ECG showed second degree AV block (Barbosa *et al.*, 2008). Antidigoxin Fab treatment restores sinus rhythm and is the only proven therapy for yellow oleander poisoning (Rajapakse, 2009).

### *Convallaria majalis* (lily of the valley)

Lily of the valley is an herbaceous perennial woodland plant native to northern climates. Cardenolides concentrations are highest in the roots, but all plant parts are

of concern. There are over 30 glycosides and convallatoxin is the most toxic with an  $\text{LD}_{50}$  of 0.08mg/kg body weight (Fenton, 2002). Convallatoxin produces cardiac toxicity by inhibiting the enzyme  $\text{Na}^+/\text{K}^+$ -ATPase. Overdose causes intoxication, sinus tachycardia, heart block and fibrillation, culminating in cardiac arrest. Cats are extremely sensitive to lilies, with the ingestion of two leaves resulting in death (Fitzgerald, 2010). Fluid diuresis, before the onset of renal failure, has been used as treatment.

### *Rhododendron* spp. (azalea, rhododendron)

Rhododendron is a genus of over 600 species that includes azalea. Its toxic principle is grayanotoxin (Aker *et al.*, 1976), a compound that inhibits  $\text{Na}^+/\text{K}^+$ -ATPase. The grayanotoxin binds to the muscarinic receptors. Bradycardia results from the peripheral vagal stimulation. Severe cases lead to cardiovascular collapse. The toxic principle interferes with cardiac muscle and clinical effects are apparent several hours post-ingestion (Sharma *et al.*, 2009). Cardiovascular symptoms include hypotension, cardiac arrhythmias and weak heart rate. The severity of toxicity also depends on the route of exposure. The  $\text{LD}_{50}$  in mice is 5.1mg/kg body weight (Barceloux, 2008). Treatment is symptomatic.

### *Kalmia* spp. (laurel, lambkill)

Laurel is an evergreen shrub of the family *Ericaceae*, native to North America. The plant contains the glycoside grayanotoxin which is toxic to ruminants. The  $\text{LD}_{50}$  in rats is 2–5mg/kg body weight (Frohne and Pfander, 2005). Minimum toxic dose in cattle is 0.4% body weight (Beasley, 1999).

A grayanotoxin, also known as acetylandromedol, binds to the sodium ion channel receptors involved with activation and inactivation of the cells. With inactivation blocked, the excitable cells remain depolarized. Cardiac symptoms include low blood pressure, bradycardia and also ventricular tachycardia.

Therapy includes atropine and also vasopressors to raise the blood pressure. Arrhythmias produced by grayanotoxin I can be reversed by tetrodotoxin (Aker *et al.*, 1976; Ku *et al.*, 1977).

## CYANIDE-CONTAINING PLANTS

Approximately 2500 plants contain cyanogenic glycosides (Vetter, 2000). Hydrocyanic acid/prussic acid is

commonly formed in the seeds and leaves of sorghum plants and also from cassava. It is a rapidly acting poison that inhibits the action of enzymes (cytochrome oxidase) that links oxygen with the erythrocytes. Plants with only 20mg of cyanogenic glycosides per 100g (Allison and Baker, 2007) can kill livestock by asphyxia. By inhibiting cytochrome oxidase, cyanide induces cellular hypoxia. Since oxygen cannot be utilized, ATP is no longer formed. Cardiac symptoms include tachycardia, dysarrhythmia and petechial hemorrhage of the heart and other organs. ECG changes include elevation or depression and shortened ST-segment, fusion of the T-wave and QRS segment (Holstege *et al.*, 2010). The amount of hydrocyanic acid formed by a plant varies, but the lethal dose for a mouse is 3.7mg/kg body weight and for cattle and sheep it is 2.0mg/kg body weight (Speijers, 2003). Plants containing cyanogenic glycosides in excess of 20mg/100g of plant material are avoided in feedstock.

Ruminants are more likely to be poisoned than monogastric animals (horses and pigs) because the lower pH in the stomach of monogastric animals destroys enzymes that convert cyanogenic glycosides to hydrocyanic acid.

Antidotes include sodium nitrite and sodium thiosulfate.

ALKALOID-CONTAINING PLANTS  
(SEE TABLE 16.2)

The alkaloids from plants of roughly 20 families are known to exert cardiac toxicity. These alkaloids are the

polycyclic diterpenes that act as neuromuscular blocking agents. There are two classes of steroidal alkaloids; solanum and veratridine (Schep *et al.*, 2006). The solanine alkaloid opens the potassium channels of mitochondria and increases Ca<sup>++</sup>, while tropane alkaloids are anticholinergic and cause arrhythmias, bradycardia and tachycardia. Common plants that contain toxic alkaloid(s) include Larkspur, yew, monkshood, ground hemlock and death camas. The lily family contains the alkaloid veratridine that causes persistent opening of voltage-gated sodium channel and significantly reduces channel conductance.

*Delphinium* spp. (larkspurs)

Larkspurs consist of 250 species of annual and biennial flowering plants of the buttercup family *Ranunculaceae*, distributed throughout the Northern Hemisphere. Their ingestion has been responsible for extensive losses in cattle (Pfister *et al.*, 1999; Green *et al.*, 2009a; Green *et al.*, 2009b). The plant contains numerous norditerpenoid alkaloids and their toxicity greatly varies (Panter *et al.*, 2002; Welch *et al.*, 2008). Three alkaloids are of major concern: methyllycacontine (MLA), 14-deacetylnudicauline (DAN) and nudicauline (NUD). The LD<sub>50</sub> is 25–40mg/kg body weight, depending on the type of alkaloid present.

Intoxication occurs when the nicotinic acetylcholine receptors are blocked. There are species differences in the symptoms, but the usual cardiac signs include rapid and irregular heartbeat and hypotension. The effect of larkspurs alkaloids are counterbalanced by the anticholinesterase agent, such as neostigmine or physostigmine. Anticholinesterases alleviate the clinical symptoms

TABLE 16.2 Alkaloid-containing plants

Botanical name	Common designation	Cardiac symptoms	Ancillary cardiac effect	Toxicity
<i>Delphinium</i> spp.	Larkspur	irregular tachycardia	methyllycaconitine is antagonistic of nicotinic receptors; important role in poisoning of livestock	LD50 (cattle) 25–40mg/kg b.w.
<i>Aconitum</i>	Monkshood	hypotension, myocardial depression, conduction disturbance, tachycardia	contains methyllycaconitine acts as NM blocking agent	LD50 (mice) 130–280mg/kg b.w.
<i>Taxus</i> spp.	Yew	bradycardia, acute cardiac failure	depresses conduction of depolarization through the heart, no significant lesions	LD50 (rabbit) 8mg/kg b.w., LD50 (mice) 15mg/kg b.w.
<i>Zygadenus</i> spp.	Death camas	weak, irregular pulse, decrease in blood pressure due to dilation of arterioles	constricting veins, no specific lesions on autopsy, sheep especially vulnerable	sheep lethal dose: 0.6–6% b.w.
<i>Eupatorium rugosum</i>	White snakeroot	congestive heart failure	cardiac muscle degeneration	0.5–2.0% b.w. consumption intoxicates
<i>Astragalus</i>	Locoweed	congestive right-heart failure	accumulates selenium, heart affected	toxin content greater than 0.001% causes poisoning

in cattle (Green *et al.*, 2009a). Physostigmine given IV at the rate of 0.08 mg/kg body weight has been used under field conditions to relieve symptoms, and may need to be repeated.

### ***Aconitum* (monkshood)**

Monkshood is a herbaceous perennial found in elevated regions of the Northern Hemisphere. All parts of the plant are poisonous and contain polycyclic diterpene alkaloids mainly of the aconitine type. These alkaloids have affinity for the open state of the voltage-sensitive  $\text{Na}^+$  channel making them refractory to excitation (Chan, 2009). The resting  $\text{Na}^+$  permeability of excitable cells is increased, resulting in incomplete inactivation of  $\text{Na}^+$  channels in nerves (persistent activation) and a decrease in ion selectivity. This causes depolarization of resting nerve and muscle and an increase in repetitive discharge. With low dosage there is stimulation of medullary vagal centers, causing decreased heart rate and blood pressure. Higher dosage of aconitine predisposes to a variety of arrhythmias, including atrial flutter and fibrillation, due in part apparently to the complex effects of aconitine on the CNS, which in turn affect the adrenergic and cholinergic systems (Burrows and Tyrl, 2001). The  $\text{LD}_{50}$  in mice for aconitine is 130–280 mg/kg body weight, depending on the plant. Aconitine causes hypotension, bradycardia, ventricular tachycardia and conduction disturbances. Treatment is symptomatic and supportive.

### ***Taxus* spp. (yew)**

The yew is an evergreen shrub found throughout North America. Ingestion of clippings from the plant causes poisoning in ruminants as well as in monogastrics. The toxic principles, taxine A and B alkaloids, cause an increase in the cytoplasmic  $\text{Ca}^{2+}$  and interfere with  $\text{Na}^+$  and  $\text{Ca}^{2+}$  ion channel conductance that precedes bradycardia and diastolic cardiac arrest. Taxine B induces increased AV conduction times, longer QRS and an absence of P-waves on ECG (Tiworthy *et al.*, 2005).

In ruminants, 0.5% of body weight, and in monogastrics (horses), 0.1% of body weight, ingestion is enough to cause clinical signs of toxicity. In mice, the  $\text{LD}_{50}$  is 15 mg/kg body weight and cardiac symptoms include arrhythmias, possibly culminating in cardiac failure (Wilson *et al.*, 2001).

Observed blockade of  $\text{Na}^+$  or  $\text{Ca}^{2+}$  channels also causes the Brugada-like syndrome (Veltmann *et al.*, 2009). No specific treatment is known for yew poisoning except atropine and lidocaine for symptoms and treatment directed toward stabilization of cardiovascular function.

### ***Zigadenus venenosus* (death camas)**

Death camas is an abundant perennial plant found in western states. It grows early in the spring but enters dormancy when soil moisture declines. It is poisonous to livestock upon ingestion, with death occurring within a few hours. The toxic principle is the cevanine steroidal alkaloid, i.e., zigacine (Beasley, 1999). In sheep 0.6–6% of body weight ingestion is fatal. Zigacine causes weak, fast, irregular pulse, bradycardia, drop in blood pressure, necrosis of cardiac muscle and cardiovascular failure. There is no known treatment for death camas poisoning.

### ***Cicuta maculata* (water hemlock)**

Water hemlock is one of the most toxic plants found in North America (Panter *et al.*, 1988). Water hemlock is a biennial and tall plant and grows in wet surroundings. The toxic principle is cicutoxin which affects the central nervous system. It acts on the GABA (gamma-aminobutyric acid) receptor, blocking the  $\text{Cl}^-$  channel that causes neuronal depolarization and seizures. Death occurs due to respiratory failure. One g/kg body weight will kill sheep and 230 g horses and cattle. Due to its severe toxicity in cattle, it is also called “cowbane.”

Cardiovascular effects include alterations in blood pressure, heart rate, a widening of the PR interval on the ECG, supraventricular tachycardia and ventricular fibrillation (Schep *et al.*, 2009). Degeneration and fibrosis in the heart is observed and the blood serum shows increases in AST and LDH, enzymes which are released upon injury to the heart or liver.

Treatment, though difficult and usually not in time due to the rapidity of the poisoning, includes intravenous administration of barbiturates to control seizures.

### ***Eupatorium rugosum* (white snakeroot)**

White snakeroot is a member of the *Asteraceae* family native to the eastern United States. An erect plant is up to 1.5 meters tall with the leaves resembling those of the nettle. Consumption of plants at 0.5–2.0% of body weight causes poisoning in livestock (Doyle *et al.*, 1949). The plants are poisonous to horses, goats and sheep. White snakeroot contains the toxin tremetol. Tremetol passes through the milk in cows, and thus contaminated milk causes sickness in suckling calves and humans. It is important to mention that tremetol is cumulative in that repeated exposure leads to intoxication.

The onset of clinical signs begins 2 to 3 weeks post-ingestion. In horses it causes congestive heart failure (Maratea, 2003). The enzymes CK, ALP (alkaline

phosphatase) and AST are elevated and cardiac muscle degeneration occurs. Pale linear streaks in the myocardium, as well as fluid in the pericardiac sac, have been observed. In horses, swelling in the neck area is also noted. Rapid heart rate, elevation of ST and variable QRS complexes in the ECG and cardiac arrhythmias may be present. Treatment consists of supportive care.

### *Astragalus* (locoweed)

Locoweed is found throughout the western United States and Canada. This perennial plant contains the toxic principle indolizidine alkaloid swainsonine, and is toxic to livestock. A toxic content of locoweed greater than 0.001% can cause poisoning. Cytoplasmic vacuolation of cells of the central nervous system occurs. It increases the severity of "high mountain disease," a hypoxia-induced pulmonary hypertension and hypertrophy of the right ventricle of animals living at elevated altitudes. Sheep, cattle and horses are affected. Some of the *Astragalus* species also accumulate large amounts of selenium, complicating the effect on the heart.

Pathological effects include neurological damage and congestive right-heart failure. The toxin inhibits the lysosomal enzyme  $\alpha$ -mannosidase. Treatment includes fluid therapy with potassium supplementation, dopamine and diazepam.

## OXALATES

Many oxalate-containing plants, such as philodendron, are kept for their ornamental beauty and are accessible to pets. If ingested in large quantities, a significant amount of oxalates can be absorbed into the bloodstream. Oxalic acid combines with calcium and forms the crystals of calcium oxalates. Although these crystals are primarily deposited in the kidneys, they can also be deposited in other organs, including the heart. In humans, oxalosis is known to cause cardiac abnormalities, including heart block (Coltart and Hudson, 1971), which can be linked to decline in renal function (Mookadam *et al.*, 2010). Cardiac manifestation of oxalosis has not been actively pursued in animals, but some data are available. Ingestion of sodium oxalate results in weak and irregular pulse, hypotension and ultimately cardiovascular collapse (VonBurg, 1994). Sheep and cattle grazing on *Rumex crispus* (curled dock) native to Europe and Western Asia may suffer with tetany, recumbency and death.

The formation of calcium oxalates also leads to hypocalcemia which interferes with electrical activity of the

heart as it inhibits the calcium pump active in the generation of the action potential and eventually results in the relaxation of the muscles. The reduced activity of the heart can culminate in cardiac arrest.

Therapeutic measures include induction of vomiting, and oral dosing of calcium lactate to reduce further absorption of oxalates.

## GOUSIEKTE

The Rubiaceae is the fifth largest flowering plant family spread worldwide but is found mostly in the warmer climates. An economically important member of the family is *Coffea arabica*, the source of coffee beans. Gardenia (*Gardenia jasminoides*) is another plant of the frost-free zones planted worldwide.

Four to 6 weeks after ingestion of plants of the Rubiaceae family, ruminants, without forewarning, drop dead with heart failure (Kellerman, 2005). Called gousiekte (Afrikaans name meaning quick sickness), the disease affects sheep and cattle and is characterized by myocardial necrosis consisting of a loss of myofibrils, cardiac dilations and replacement of myocytes with collagenous tissue. In the terminal phase of the disease, the heart has a rounded, flabby appearance without an apex and has attenuated papillary muscles. In the subendocardial region of the apex and the left ventricular wall, the principal lesions are degeneration of myofibers.

The toxic principle pavetamine from *Pavetta harborii* inhibits myocardial protein synthesis without affecting myocardial fibers or other organs. The disease is characterized by cellular injury and is not a specific heart disease. It terminates in dilated cardiomyopathy and congestive heart failure (Hay *et al.*, 2008; Prozesky, 2008). Sheep dosed daily at 25mg/kg body weight, after 4 weeks, showed typical signs of cardiac failure with galloping heart rhythm, decrease of ejection fraction of the left ventricle (from 60 to 30%) and the pumping efficiency of the left ventricle with respect to the right ventricle decreased (van der Walt and van Rooyen, 1977). Goats fed pavetamine showed ECG changes and tachycardia. The electrophysiology of the pacemaker cells was affected. In sheep, T-wave inversion was common as was hypokalemia.

## MUSHROOMS

Some of the mushrooms are toxic and often get mixed into animal feed or ingested by pets. The toxins present

in the mushrooms are amatoxins (cyclic octapeptides) (Berger and Guss, 2005). Amatoxins inactivate RNA polymerase II in cell nuclei thereby preventing protein synthesis, and curtailing cell metabolism (Duffy, 2008; Chang, 2009).

Amatoxins cause damage to cardiac tissue, as evidenced by hemorrhage, cloudy swelling and degeneration. Elevations of cardiac enzymes (Unverir *et al.*, 2007), including CK-MB isoenzyme and myoglobin, are noted. Heart block and bradycardia have been observed. Also, sinus tachycardia and hypotension are typical clinical cardiac symptoms.

In dogs, electrolyte abnormalities and bradyarrhythmia (SA exit block and sinus arrest) symptoms reminiscent of muscarinic intoxication were noted and relieved by atropine (Lee *et al.*, 2009). Treatment aims at minimizing amatoxins absorption by administering activated charcoal and hydration maintenance.

## XENOBIOTICS THAT MAY CAUSE CARDIAC TOXICITY

### Arsenic

Although much native vegetation contains arsenic, the sources of intoxication usually are sprays or ingestion of feed contaminated by arsenic (Selby *et al.*, 1977). Arsenic in drinking water also poses an additional risk of cardiovascular effects including hypertension, prolongation of the QT portion of the ECG, indicating disorder of the heart's conduction system and favoring cardiac arrhythmia (Mordukhovich *et al.*, 2009; el Bahri and Ben Romdane, 1991).

Large doses of arsenic lower blood pressure and slow the pulse. In frogs the heart stops in diastole due to the paralysis of the motor ganglia. Since it is quick acting, cardiovascular collapse is to be expected. Treatment includes gastric lavage and intravenous administration of sodium thiosulfate.

### Ionophores

Ionophores are carboxylic polyether antibiotics that are given as feed additives to cattle. Ionophores alter the flow of cations across cell membranes and reduce Gram-positive bacteria responsible for bloat. Since ionophores have a narrow range of safety, feed mixing errors facilitate poisoning. In horses this leads to cardiac muscle damage and in cattle both skeletal and cardiac muscle damage.

The cardiac signature of the poisoning in horses manifests by prolongation of atrial and ventricular

depolarization and repolarization (Hall, 2006). Also, depression of the ST segment, absence of the P-wave, ventricular tachycardia, AV block and atrial fibrillation are noted. Cardiac lesions and heart failure occur. In cattle, QT and QRS prolongation, first degree heart block and T-wave amplitude increases are typical. In cattle also, cardiac lesions and heart failure are possible. Sheep also have cardiac muscle damage. The LD<sub>50</sub> of monensin is 2–3 mg/kg body weight in horses, 20–34 mg/kg body weight in cattle and 10–12 mg/kg body weight in sheep and goats (Doonan *et al.*, 1989).

Besides the growth-promoting function of ionophores in ruminants, it is used as a coccidiostat in poultry. Cardiac effects of infested poultry include reduced lipid levels, reduced heart weight, low heart rates and low blood pressure. Monensin has a narrow therapeutic window and intoxication causes muscle necrosis and myoglobinuria. Targets include cardiac muscles. It causes inotropism, tachycardia, cardiomyopathy and cardiac failure.

There is no antidote available for monensin poisoning.

### Fertilizers

Accidental ingestion of fertilizer can cause serious poisoning in animals (Villar *et al.*, 2003). Predominantly, though not exclusively, nitrates cause the damage. Rabbits exposed to ammonium sulfate fertilizer suffered cardiac arrest (Sato *et al.*, 1999). In another case with fertilizer containing nitrogen, phosphoric acid and potassium, the rabbits suffered hyperkalemia, hyperammonemia and metabolic acidosis that expressed itself on the cardiac system as ventricular tachycardia translating into ventricular fibrillation and death. However, no alterations were noted on histopathological examination of the heart. There is no specific antidote for fertilizer poisoning.

### Herbicides

There are a large number of herbicides, characterized by differing chemical structures, that cause various effects on the heart (Gupta, 2007). The ingestion of herbicide-treated plants can induce electrolyte abnormalities and low blood pressure.

Paraquat is a dipyridyl herbicide, which generates excess reactive oxygen species (Ge *et al.*, 2010). In rats, paraquat caused severe heart damage, including hemorrhage in the myocardium and alterations in ECG (Noguchi *et al.*, 1990). It also elicited sinus tachycardia but no arrhythmia.

An effective antidote is not available. Bentonite or fuller's earth can be given orally to detoxify bipyridyls.

## Pesticides

### Organophosphates and carbamates

Organophosphate (OP) and carbamate (CM) pesticides produce toxicity by inhibiting acetylcholinesterase (AChE) activity. Inactivation of AChE results in excessive ACh accumulation at the synapses and at neuromuscular junctions leading to an overstimulation of the muscarinic and nicotinic ACh receptors.

Classical cardiac signs of OP poisoning include prolonged QT interval, ST-T changes, sinus tachycardia or bradycardia and hypertension or hypotension (Saadeh *et al.*, 1997; Abraham *et al.*, 2001; Karki *et al.*, 2004).

The most effective antidote for OP and CM poisoning is the muscarinic receptor antagonist atropine sulfate. Against OPs, oximes are used to reactivate the inhibited AChE (Boelsterli, 2007; Kose *et al.*, 2009).

### Amitraz

Amitraz is a triazapentadiene compound used in flea collars of dogs. As an insecticide and acaricide, it exerts toxicity by inhibiting the enzyme monoamine oxidase (MAO) and works as an  $\alpha_2$ -adrenergic receptor agonist. The cardiac effects of  $\alpha_2$ -adrenergic agonists include bradycardia, first and second degree atrioventricular blockage and diminished cardiac output (Malmasi and Ghaffari, 2010). ECGs performed on an English bulldog poisoned with amitraz showed QT elongation, a precursor to ventricular arrhythmia. Amitraz apparently lengthened the QT interval by reduction of the heart rate. Thermogenesis was also affected. Hypothermia decreased the depolarization of the pacemaker cells, so that bradycardia ensued.

## ANCILLARY CAUSES OF CARDIAC TOXICITY

## Arthropods

### Scorpions and spiders

Envenomation by arthropods (scorpions and spiders) is a serious health concern to humans and animals in many countries. Scorpion venoms can exert peripheral as well as central effects (Gwaltney-Brant 2011). In general, severe envenomation by scorpions produces the signs of cardiac and respiratory rhythm, arterial hypertension that can progress to congestive heart failure, pulmonary edema and shock. There can be frequent vomiting, diarrhea, salivation and alternating restlessness with somnolence and sometimes convulsions. Effects of scorpion venom are more pronounced on the cardiac system

(Murthy *et al.*, 1999; Dorce *et al.*, 2009). In dogs and rabbits, 3.5mg/kg body weight of scorpion venom causes an increase in LDH and CK-MB enzyme levels. ECG changes in T-waves (biphasic) and ST-segment and electrical alterations indicate myocardial damage, ancillary arrhythmias, conduction defects and infarction-like patterns (Gueron *et al.*, 1992; Bentur *et al.*, 2003). Scorpion toxin includes potassium channel blocking peptides (Kumar *et al.*, 2011). The venom of the death stalker scorpion (*Leiurus quinquestriatus*) includes chlorotoxin, which blocks small conductance of chloride channels.

Treatment for a scorpion sting is symptomatic. Hypertensive symptoms are treated with vasodilators. Scorpion antivenoms are available.

### Bees, wasps, hornets, yellow jackets and ants

The venom of bees, wasps, hornets, yellow jackets and ants is poisonous. A lethal dose is approximately 20 stings/kg body weight in most mammals (Fitzgerald and Flood, 2006). The severity of the stings is increased by anaphylactic reactions.

Stings can cause myocardial infarction and myocarditis. Increases in serum enzyme levels and necrosis in the myocardium have been reported (Levine, 1976; Ferreira *et al.*, 1995). Mast cells in cardiac tissue may be affected by their mediators which have cardiotoxic effects, including arrhythmogenesis. Wasp stings can cause Mobitz Type I heart block and myocardial infarction (Wagdi *et al.*, 1994). ECG changes, myocardial necrosis and arrest of cardiac beats were noted after envenomation by Africanized honey bee venom in Wistar rats. Honeybee sting can produce significant elevations of the ST-segment, CK-MB activity and troponin I and T levels.

Treatment includes antihistamines, steroids, bronchodilators and  $\alpha$  and  $\beta$ -receptor agonists.

### Snakes

Six hundred known venomous snakes belong to the following four families: atractaspidids, colubrids, elapids and viperids. The crotalids include pit vipers, moccasins and rattlesnakes while coral snakes belong to the elapids.

Snake venom contains biologically active ingredients with cytotoxic, neurotoxic and anticoagulant effects. From the cardiac system point of view, the phosphodiesterases that lower blood pressure and phospholipase A2 that causes hemolysis are most significant.

The subcutaneous LD<sub>50</sub> of cottonmouth (*Agkistrodon piscivorus*) venom is 25.8mg/kg body weight, for *Vipera berus* is 6.45mg/kg body weight and for *Vipera latifii* is 4.61mg/kg body weight. Disruption of the normal blood clotting pathways is significant. Some prevent clot formation, inducing hemorrhagic shock. Other toxins induce clotting, causing stroke and heart attacks by blocking blood flow.

Cardiotoxins bind to muscle cells causing depolarization and prevention of muscle contraction, thus interfering with the rhythm of the heart. Snake bites usually are noted in dogs bitten on the head or neck. In one particular study, cardiac variables were normal on auscultation at admittance, post-envenomation. Twenty-four hours later, 11% had cardiac abnormalities. Muscle damage as evidenced by elevated CK values in serum biochemistry was noted in 54% of sampled dogs (Segev *et al.*, 2008; Lervik *et al.*, 2010). The myocardial injury was verified by ECG performed post-envenomation. Myocardial damage post-envenomation was also shown by the increase of cardiac-specific troponin I.

Polyvalent antivenoms are available for the treatment of most pit viper bites. Coral snake bites require neurotoxic antivenom.

### Blister beetles

Blister beetles prefer alfalfa fields where large swarms tend to congregate. When these fields are harvested, the blister beetles are crushed and incorporated into the bales of hay. They contain a poisonous substance known as cantharidin. It is an inhibitor of the serine-threonine protein phosphatase. Cantharidin blocks the adenosine A<sub>1</sub> receptors, which regulate myocardial oxygen consumption, yielding anti-adrenergic effect in ventricular cardiac myocytes (Narayan *et al.*, 2000). Cantharidin can exert a positive inotropic effect in cardiac muscle by increasing calcium influx (Neumann *et al.*, 1995).

In equids, the LD<sub>50</sub> of cantharidin is reported to be 1 mg/kg body weight (Guglick *et al.*, 1996). A dose of 4 g of dried beetles is lethal to a horse and 1–1.5 mg/kg body weight is lethal to cats and dogs. The cardiac symptoms of cantharidin poisoning include increased heart rate and myocardial dysfunction.

There is no antidote for cantharidin but symptomatic treatment is recommended with administration of fluids and maintenance of serum electrolytes.

## CONCLUSIONS AND FUTURE DIRECTIONS

Cardiac problems in domestic animals are primarily due to toxic plants, chemicals and envenomation, most of which can be avoided. There is only a limited amount of published research on cases involving inadvertently affected animals. Animal cardiac responses have been extensively studied in the development of drugs. A considerable amount of work still needs to be done on cardiotoxicity in animals caused outside of drug development.

## Liver toxicity

Motoko Mukai, Karyn Bischoff and Shashi K. Ramaiah

### INTRODUCTION

The liver is a remarkable organ that usually protects the individual against injury from xenobiotic compounds. The liver is susceptible to injuries by chemical compounds because it is often the site of metabolism and it is where some chemicals concentrate and become bioactivated. Although its capacity for repair and regeneration (Ramaiah *et al.*, 2004; Mehendale, 2005) makes it a quite robust organ, if the ability to regenerate is not adequate, or if injury to the liver is very severe, liver damage may progress to liver failure and death.

There is continued interest concerning the higher incidence of liver damage caused by prescription/injectable drugs, over-the-counter medications or dietary supplements that are often combined with special diets and alcohol consumption, in addition to environmental chemicals/xenobiotics (Watkins, 1999). Though alcohol consumption is not a major risk factor in most veterinary patients, other factors such as toxic pasture or house plants, cyanobacterial toxins, pollutants, fungal toxins and toxicants in household waste are associated with hepatic injury. An incomplete list of hepatotoxins is found in Table 17.1. Complicating matters is the increasing population of geriatric veterinary patients. Preexisting liver disease must be considered in patients exposed to liver toxicants.

In humans, drug-induced liver injury has become the most frequent cause of acute liver failure in the United States and around the world, exceeding all other causes combined. Although the incidence of idiosyncratic drug-induced liver injury (DILI) with approved drugs at therapeutic doses is relatively low and estimated at 1 to 10

per 100,000 treated patients, the outcome is potentially a very grave one. Approximately 10% of those human patients will die or require liver transplantation, making idiosyncratic DILI the leading causes for urgent liver transplantation (Stirnemann *et al.*, 2010). Toxic liver disease also remains the single major cause for regulatory actions concerning drugs. Such actions may include failure of approval, withdrawal from the market, restrictions on use and warnings to physicians.

Liver injury by xenobiotics is also encountered in a variety of circumstances. Some natural toxins such as the cyclic peptides of *Amanita phalloides*, pyrrolizidine alkaloids, cycasin from cycad palms and other phytochemicals are examples of environmental hazards. They may be ingested by the curious or very hungry veterinary patient. Others, such as mycotoxins, are ingested unknowingly because of feed contamination due to climatic conditions favorable to fungal growth. A striking example of this phenomenon is the recent contamination of dog food with aflatoxin resulting in dozens of canine deaths in late 2005 and early 2006 (Stenske *et al.*, 2006; Newman *et al.*, 2007; Dereszyński *et al.*, 2008). Other circumstances of exposure to hepatotoxins in the home or farm include accidental food or feed contamination with industrial chemicals or pesticides. For example, in 1955, a human outbreak of hepatic porphyria in Turkey (Can and Nigogosyan, 1963) was caused by ingestion of wheat to which hexachlorobenzene, a fungistatic agent, had been added.

The goal of this chapter is to provide a basic understanding of the liver physiology and pathophysiology, and to expand on the common toxicosis inducing liver injury in veterinary medicine.

TABLE 17.1 Incomplete list of hepatotoxins of veterinary interest

Classification of mechanism	Toxicant	Source of toxicant	Source classification	Species affected	
Free radical	Carbon tetrachloride	Cleaning agents	Industrial	All	
	Yellow phosphorus	Fireworks	Industrial	All	
	Iron	Dietary supplement	Household	All	
	Copper	Dietary supplement	Feed, industrial	Sheep, some dog breeds	
Electrophile	Aflatoxins	<i>Aspergillus</i> spp.	Mycotoxin	All	
	Acetaminophen	NSAID	Household	All, cats	
	Sesquiterpene lactones	<i>Helenium</i> spp., <i>Hymenoxis</i> spp.	Plant	Herbivores	
	Pyrrolizidine alkaloids	<i>Amsinkia</i> spp.	Plant	Herbivores	
		<i>Crotolaria</i> spp.			
		<i>Cynoglossum</i> spp.			
		<i>Echium</i> spp.			
		<i>Erechtites glomerulata</i>			
		<i>Senecio</i> spp.			
	Biliary obstruction	Sporodesmin	<i>Pithomyces chartarum</i>	Mycotoxin	Herbivores, ruminants
Sapogenins		<i>Tribulus terrestris</i>	Plant	Herbivores, ruminants	
		<i>Panicum</i> spp.	Plant	Herbivores, ruminants	
		<i>Agave lecequilla</i>	Plant	Herbivores, ruminants	
		<i>Nolina texana</i>	Plant	Herbivores, ruminants	
		<i>Cycas</i> spp.	Plant	Dogs	
Other	Glycosides of methylazocymethanol				
	Carboxyatractyloside	<i>Xanthium</i> spp.	Plant	Swine, herbivores	
	Triterpenes	<i>Lantana</i> spp.	Plant	Herbivores	
	Amatoxins	<i>Amanita</i> spp.	Mushroom	All	
	Microcystins	<i>Microcystis</i> spp.	Cyanobacteria	All	
	Nodularins	<i>Nodularia</i> spp.	Cyanobacteria	All	
	Phenolics and coal tar derivatives	Disinfectants, clay pigeons	Household	All	
	Unknown	Joint supplements	Drug	Dogs	
	Idiosyncratic	Sulfonamides	Antimicrobial	Drug	Dogs
		Carprofen	Anti-inflammatory	Drug	Dogs
Diazepam		Sedative	Drug	Cats	

## STRUCTURAL AND FUNCTIONAL ORGANIZATION OF THE LIVER

### Lobule and acinus

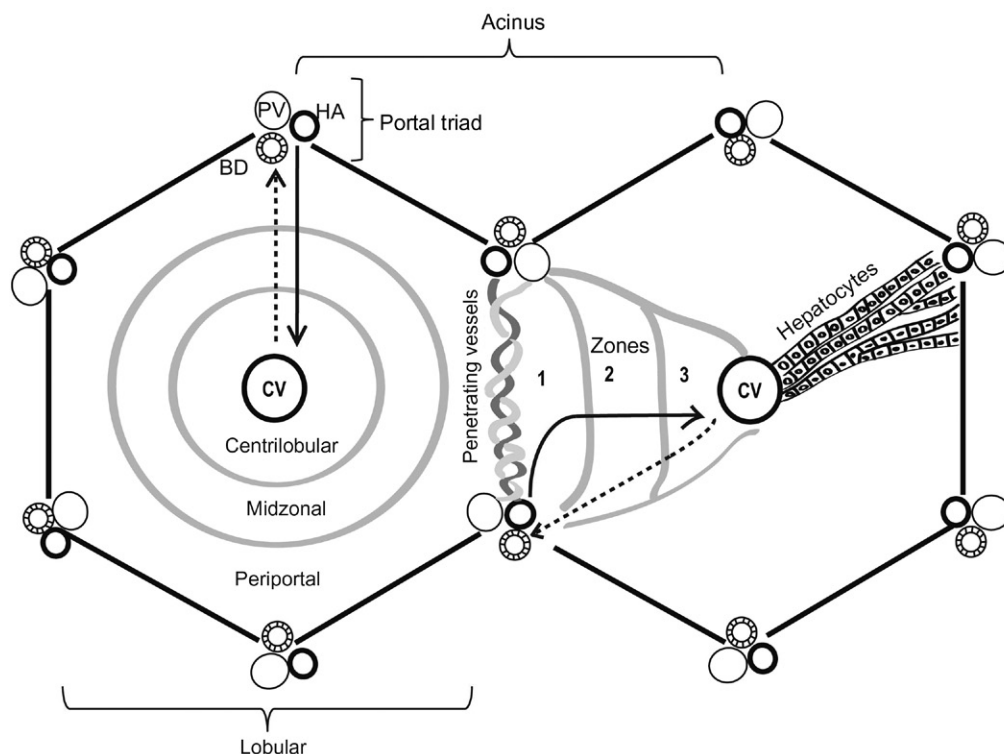

The structural and functional organization of the liver has been described by two concepts called the hepatic lobule and hepatic acinus models. The hepatic lobule, a more classical model, is defined histologically as a hexagonal region of parenchyma surrounding the central vein. Six portal triads, composed of branches from the portal vein, hepatic artery and bile ductules, border the edge of the lobule. One-cell thick plates or cords of hepatocytes are arranged radially around the central vein, forming the blood sinusoids between them. The hepatic parenchyma is divided into three zones based on proximity to the central vein (Figure 17.1, left). The area adjacent to the central vein is termed *centrilobular*, the area adjacent to the portal triad is *periportal*, and between the centrilobular and periportal parenchyma is the *midzonal* area.

The hepatic acinus, on the other hand, was defined by Rappaport as the smallest structural and functional unit in the liver based on the microcirculation in the liver, and is preferred as a concept of a functional hepatic unit (Figure 17.1, right). The blood in the liver flows from the portal vein and hepatic artery of the portal triad, is mixed in the penetrating vessels, enters the sinusoids, and eventually exits via central hepatic vein. The cells of the acinus are arbitrarily divided into three zones according to the sequence of the blood flow: *zone 1* corresponds to the periportal zone, *zone 2* corresponds to the midzonal area, and *zone 3* corresponds to the centrilobular zone.

### Diverse function of the liver

The liver is a functionally diverse organ. The liver is directly involved in (1) nutrient homeostasis, including glucose regulation (Treinen-Moslen, 2001; Pineiro-Carrero and Pineiro, 2004), cholesterol synthesis and uptake (Treinen-Moslen, 2001), storage of glycogen,

**FIGURE 17.1** Lobular versus acinar concept in liver architecture. The hepatic lobule is defined histologically as a hexagonal region of parenchyma surrounding the central hepatic vein. The hepatic acinus is a functional unit based on the microcirculation of the liver, and is preferred as a concept of a functional hepatic unit. The hepatic parenchyma is divided into three sections based on proximity to the central vein in the case of lobular model (centrilobular, midzonal, periportal), and according to the sequence of the blood flow in the case of acinar model (zones 1–3). Blood flows towards the central vein (solid line) and bile flow towards to bile duct (dotted line). CV: hepatic central vein, BD: bile duct, HA: hepatic artery, PV: portal vein.

lipids, minerals and vitamins (Plumlee, 2004), (2) synthesis of clotting factors, albumin, very low density lipoprotein and other proteins (Treinen-Moslen, 2001; Plumlee, 2004) and (3) metabolism and excretion of such things as hemoglobin breakdown products (Plumlee, 2004), steroid hormones (Brown, 2001) and xenobiotics.

Blood from the gastrointestinal tract, via the portal vein, is filtered for bacterial products, such as endotoxin and ammonia, and xenobiotics (Treinen-Moslen, 2001; Plumlee, 2004). Energy-dependent transport exists for certain xenobiotics and endogenous hormones. These include a group of multiple drug resistance p-glycoproteins that transport lipophilic cationic drugs, estrogens and phospholipids, as well as the canalicular multiple organic anion transporters involved in movement of molecules conjugated to glutathione, glucuronide and sulfate. Metal and mineral transport functions are important for mineral homeostasis and occur through facilitated diffusion and receptor mediated endocytosis across the sinusoidal membrane. Lysosomes within hepatocytes are involved in storage and export of metals and minerals into canaliculi.

Sinusoids are located between cords of hepatocytes, which are larger than capillaries and lined by

specialized endothelium. The endothelial lining is discontinuous, the sinusoidal endothelial cells having fenestrae, to allow movement of fluid and molecules less than 259 kDa into the space of Disse, located between the endothelium and the hepatocytes (Watkins, 1999; Treinen-Moslen, 2001; Plumlee, 2004). Within the space of Disse, hepatocytes contact free and protein bound molecules which may be absorbed by diffusion or aforementioned active transport (Watkins, 1999). Remarkable metabolic diversity of the hepatic zones is needed in order to accommodate the liver's numerous functions. Zone 3 hepatocytes are involved in glycolysis and lipogenesis, and zone 1 hepatocytes are involved in bile salt extraction, fatty acid oxidation, gluconeogenesis and protein synthesis and thus are rich in mitochondria for energy production (Treinen-Moslen, 2001; Pineiro-Carrero and Pineiro, 2004; Plumlee, 2004). Gradients of metabolic enzymes involved in bioactivation and detoxification have been shown along different zones of the acinus (reviewed by Jungermann and Katz, 1989). Zone 3 is particularly rich in phase I metabolic enzymes and zone 1 has highest glutathione levels involved in phase II metabolism.

The blood supply of the liver is mainly from the portal vasculature: 60 to 80% from branches of the portal vein, which supplies nutrients, drug substance and toxins from the gastrointestinal tract but is oxygen depleted, and 20 to 40% from the hepatic artery, which is oxygenated (Treinen-Moslen, 2001). Oxygen is quickly consumed to meet the high metabolic demands of the parenchymal cells as the blood flows towards the terminal hepatic venule, also known as central vein. As a consequent of this structure, hepatocytes in zone 1 receive blood that is 9 to 13% oxygenated whereas blood received by zone 3 is only 4 to 5% oxygenated and nutrient depleted (Sturgill and Lambert, 1997; Treinen-Moslen, 2001). Therefore zone 3 or the centrilobular zone has substantially lower oxygen concentrations compared to the rest of the tissue and is susceptible to hypoxia.

Another well-known gradient seen in acinar zonation is that of bile. Bile salts and bilirubin from blood enter hepatocytes via active transporters on the sinusoidal membrane, and are then secreted into canalicular lumen via canalicular membrane (Treinen-Moslen, 2001). Bile canaliculi are dynamic structures located between hepatocytes and formed by the hepatocyte membranes (Treinen-Moslen, 2001; Plumlee, 2004). Bile flows from hepatocytes, into canaliculi, and towards the direction of the bile duct of the portal triad in the liver acinus, from zone 3 to 1, in the opposite direction of the blood flow. Bile salts are efficiently extracted in zone 1 and there is little uptake by the time blood reaches zone 3.

Bile secretion is a major hepatic function essential for uptake of lipid nutrients, for protection against oxidative insults in the small intestine and for excretion of endogenous and xenobiotic compounds. Bile is composed of bile salts, bilirubin, glutathione, phospholipids, cholesterol, proteins, organic anions, metals and conjugated xenobiotics (Treinen-Moslen, 2001; Pineiro-Carrero and Pineiro, 2004).

Canaliculi enter canals of Hering in the portal triad that lead to interlobular and intrahepatic bile ducts, surrounded by bile duct epithelial cells, which coalesce to form the hepatic bile duct. Most animal species have a gall bladder for bile storage but others lack them, including horses and related species, rhinoceroses and tapirs, elephants, camelids, porcupines, pigeons, rats, deer, ratites and many parrots. Gall bladders may or may not be present in some species such as giraffes and hippopotamuses (Oldham-Ott and Gilloteaux, 1997). Most carnivores have a gall bladder, the exceptions being dolphins and other cetaceans.

The gall bladder stores and concentrates bile, then empties into the duodenum. When the gall bladder is absent, bile empties directly into the duodenum (Ramaiah, 2007). Bile enhances nutrient uptake in the small intestine, protects enterocytes from oxidation and facilitates excretion of xenobiotics and endogenous waste in the feces (Treinen-Moslen, 2001).

## Cell types of the liver

Seven intrinsic cell types have been identified in the liver: the parenchymal cells (or hepatocytes), the hepatocytic stem cells (oval cells) and five non-parenchymal cell types. Non-parenchymal cells include bile duct epithelial cells, sinusoidal endothelial cells, described above, as well as the resident macrophages (Kupffer cells), the large granular lymphocytes (pit cells) and the lipid storing hepatic stellate cells (HSC or Ito cells). Hepatocytes represent about 60% of the total cell number and 80% of hepatic tissue volume in the rat liver, and non-parenchymal cells are estimated to constitute about 30% of total cellular population, but only 6–7% of tissue volume due to their smaller size (Dahm and Jones, 1996).

Oval cells, the hepatocytic stem cells, are located in the canals of Hering, where bile canaliculi from the hepatic cords converge with bile ductules of the portal triad. If the hepatocyte replication is impaired, the oval cells proliferate and differentiate to eventually become both hepatocytes and biliary epithelial cells (Fausto and Campbell, 2003; Jaeschke, 2008). Experimental blockade of hepatocyte proliferation can potentially lead to continued oval cell proliferation leading to neoplastic transformation of hepatocytes resulting in hepatocellular tumors. New hepatocytes progress down hepatic cords to replace the aging zone 3 hepatocytes.

Kupffer cells represent 80% of the fixed macrophages in the body (Treinen-Moslen, 2001). These macrophages are usually located within sinusoids and are closely associated with endothelial cells. Kupffer cells are phagocytes, ingesting foreign material from the portal circulation (Treinen-Moslen, 2001; Plumlee, 2004) and debris from apoptotic or necrotic hepatocytes. Kupffer cells have other immune functions. They act as antigen presenting cells and secrete various cytokines (Treinen-Moslen, 2001; Plumlee, 2004), and are involved in destruction of metastatic neoplastic cells (Plumlee, 2004). Kupffer cells may store minerals and are involved in the pathogenesis of a variety of liver diseases induced by toxins such as ethanol (Laskin, 1990; Thurman, 1998).

Pit cells are natural killer cells with antineoplastic functions and are involved in granuloma formation and reside within sinusoids (Treinen-Moslen, 2001; Plumlee, 2004). Pit cells can proliferate locally when stimulated and attack tumor cells together with Kupffer cells (Wisse *et al.*, 1997).

Hepatic stellate cells (HSCs) or Ito cells are located in space of Disse and store fat and vitamin A (Treinen-Moslen, 2001; Pineiro-Carrero and Pineiro, 2004; Plumlee, 2004). When there is liver injury, HSCs are activated to myofibroblast-like cells (Plumlee, 2004; Maddrey, 2005). Activated stellate cells produce collagen and play a role in hepatic fibrosis (Treinen-Moslen, 2001; Plumlee, 2004).

## FACTORS INFLUENCING TOXIC LIVER INJURY

### Uptake and concentration

The liver has a dual blood supply as noted above. The hepatic artery brings blood from the systemic circulation and the portal system brings blood directly from the gastrointestinal system. The portal system is involved in the "first pass effect," meaning that nutrients and xenobiotics absorbed by the digestive system are filtered through the liver before entering the systemic circulation (Treinen-Moslen, 2001).

The space of Disse allows close contact between circulating plasma, plasma proteins and hepatocytes, allowing rapid diffusion of lipophilic compounds across the hepatocyte membrane (Treinen-Moslen, 2001). Some compounds are specifically taken up by sinusoidal transporters, including bile acids, phalloidin from several *Amanita* spp. of mushrooms, and microcystin produced by the cyanobacteria *Microcystis aeruginosa*.

Liver cells can accumulate high levels of metals and vitamins, leading to injury. For example, excessive storage of vitamin A in stellate cells produces engorgement, activation and proliferation of these cells (Treinen-Moslen, 2001). Chronic high vitamin E concentrations produce hepatic fibrosis and portal hypertension in humans, precipitating continued fibrosis (Zimmerman, 1999; Pineiro-Carrero and Pineiro, 2004; Maddrey, 2005). Cadmium is sequestered by hepatic metallothioneins but produces pathology when storage capacity is exceeded.

The liver is also responsible for iron homeostasis. Iron uptake from the sinusoids is receptor mediated and sequestration uses iron storage proteins such as ferritin. High hepatic iron concentrations produce lipid peroxidation affecting zone 1 hepatocytes (Treinen-Moslen, 2001). Certain bird species such as toucans, aracari, mynahs and birds of paradise often have hemosiderosis, accumulation of iron in the liver, and are prone to hemochromatosis, a disease state of iron build-up. Increased expression of iron transporters DMT1 and Ireg1 has been found in one of the susceptible species, mynahs, which are likely to be the cause of iron accumulation in this particular species (Mete *et al.*, 2005). However, the genetic cause(s) in mynahs or other susceptible avian species has not been completely determined yet.

The liver also plays an important role in copper homeostasis. Inability to export copper into bile is the cause of Wilson's disease in humans. This disease is caused by a defect or lack of an autosomal recessive gene called P-type ATPase (ATP7B), a copper transporter (Jaeschke, 2008). Similar copper storage disease of veterinary relevance, either mediating or as a result of chronic liver damage, is noted in certain breeds of dogs: Bedlington

terriers, West Highland white terriers, Skye terriers, Dalmatians, Doberman pinschers, Labrador retrievers, Anatolian shepherds, cocker spaniels, poodles and others (Rolfe and Twedt, 1995; Spee *et al.*, 2006). Recently, deletion of exon 2 of the MURR1 (COMMD1) gene, important in regulation of copper excretion into bile, was found to be the genetic defect found in Bedlington terriers (Klomp *et al.*, 2003), although molecular background of all other breeds are still unknown. Sheep are also susceptible to copper storage disease, which usually presents acutely.

Ability to excrete a toxicant into the biliary duct will usually result in clearance by excretion in feces or urine. However, certain lipophilic compounds such as methylmercury and diclofenac are commonly reabsorbed from the intestinal lumen back into the system, a process known as *enterohepatic cycling*. This will lead to long biological half-life and increased toxicity of the compound (Jaeschke, 2008).

### Bioactivation and metabolism

One of the major functions of the liver is elimination of both endogenous and exogenous compounds (xenobiotics). Most xenobiotic agents absorbed by the small intestine are highly lipophilic. Renal excretion is the primary mechanism of removal for many xenobiotics, but renal excretion of lipophilic compounds, which are frequently protein bound in the circulation, is poor (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Watkins, 1999). In order for these xenobiotics to be eliminated, biotransformation needs to occur in the liver first to increase their water solubility for excretion.

Hepatocytes contain high levels of phase I enzyme, which exposes or introduces functional groups ( $-OH$ ,  $-NH_2$ ,  $-SH$  or  $-COOH$ ) and generates reactive electrophilic metabolites. They also have a wide variety of phase II enzymes which enhance the hydrophilicity by adding a polar group by conjugation reaction to allow excretion. The functional groups exposed or introduced by the phase I reaction often become the site of action for the phase II reaction. These reactions often function in the detoxification of compounds, but there is significant potential for accumulation of toxic metabolites if the phase I and II reactions are not appropriately balanced (Zimmerman, 1999; Jaeschke, 2008).

Phase I reactions, ubiquitous in mammals, involve oxidation, reduction and hydrolysis, and sometimes produce biologically active metabolites (Brown, 2001). Phase I enzymes are predominantly located in zone 3, as mentioned previously. Many of these phase I enzymes are present in the smooth endoplasmic reticulum of the hepatocyte. When liver tissue is homogenized mechanically in a laboratory, the endoplasmic reticulum breaks

down into small vesicles known as microsomes and can be retrieved by differential centrifugation. Thus these enzymes are often referred to as microsomal enzymes. As a rule, microsomal enzymes require oxygen and NADPH to function (Dahm and Jones, 1996; Brown, 2001).

Oxidation is the major phase I reaction. Important substrates include steroid hormones and lipid soluble drugs (Brown, 2001). Oxidative reactions can produce highly reactive epoxides, which are usually detoxified rapidly by phase II conjugation or hydrolysis by microsomal epoxide hydrolase enzymes (Watkins, 1999; Pineiro-Carrero and Pineiro, 2004). If an individual is exposed to the xenobiotic in high enough doses that these mechanisms are overwhelmed, reactive phase I metabolites produce injury.

The cytochrome P450 enzymes, a major group of the microsomal enzymes, are the most common players of phase I oxidation. All P450 enzymes contain a heme iron center and when complexed within carbon monoxide, absorb light at a wavelength of 450nm. These enzymes were first discovered in an unknown pigment thus named cytochrome P450: P for pigment and 450 for the wavelength of absorbed light. Liver P450 enzymes involved in xenobiotic biotransformation belong to three main P450 gene families, CYP1, CYP2 and CYP3. More than 36 cytochrome P450 isoenzymes have been identified in animals (Dahm and Jones, 1996; Watkins, 1999; Jaeschke, 2008). P450s can be induced or inhibited by drugs such as phenobarbital and cimetidine, respectively.

Non-cytochrome P450 enzymes are also involved in oxidative reactions. One such enzyme is alcohol dehydrogenase, a cytosolic enzyme, whose substrates include vitamin A, ethanol and ethylene glycol. Others include aldehyde dehydrogenase, aldehyde oxidase, xanthine oxidase, monoamine oxidase, diamine oxidase, peroxidase and flavin-monooxygenases (Jaeschke, 2008).

Examples of phase I reduction include nitro compounds, which are reduced to amines, and volatile anesthetics, which undergo dehalogenation. Phase I hydrolysis reactions are required for metabolism of compounds with amide bonds or ester linkages, as in the conversion of aspirin to salicylate (Brown, 2001). Carboxylesterase, alkaline phosphatase, peptidase and epoxide hydrolase are involved in phase I hydrolysis reactions (Jaeschke, 2008).

Most phase II enzymes are cytosolic but others are mitochondrial or microsomal. Phase II enzymes are predominantly involved in conjugating xenobiotics at the functional groups of the parent compound or the phase I metabolites. Unlike the phase I metabolites, phase II metabolites are rarely reactive, with some exceptions such as the glucuronide of some nonsteroidal anti-inflammatory drugs and the aromatic amines (Jaeschke, 2008), which will be discussed later.

Phase II enzymes conjugate a polar group to a hydroxyl-, carboxyl-, amino- or sulfhydryl-group on the substrate. Polar molecules added to substrates include glucuronic acid, sulfate derived from sulfuric acid ester, acetate, glutathione, methyl groups derived from methionine and amino acids such as glycine and cysteine. These groups enhance water solubility to allow for renal or biliary excretion of the metabolite. Disruption of phase II reactions allows accumulation of reactive phase I metabolites (Sturgill and Lambert, 1997).

Glucuronidation is the most common phase II reaction in humans, though it is deficient in the neonate and, of significant veterinary importance, in cats (Sturgill and Lambert, 1997; Brown, 2001; Pineiro-Carrero and Pineiro, 2004). Substrates with a molecular weight greater than 500, such as steroid hormones, thyroxine, bilirubin, salicylates, acetaminophen and many other drugs, are likely to undergo glucuronide conjugation. Glucuronyltransferases are microsomal enzymes that catalyze the transfer of glucuronide from uridine 5'-diphosphate (UDP). UDP becomes depleted in overdoses of acetaminophen and other drugs that undergo this detoxification pathway. Products of glucuronide conjugation are excreted in the bile or urine. Those excreted in the bile sometimes undergo hydrolysis in the intestine, leading to *enterohepatic cycling*. Phenobarbital is one agent that induces glucuronyltransferases.

Sulfation is the primary conjugation reaction for aliphatic alcohols and substrates with phenol groups (Sturgill and Lambert, 1997; Brown, 2001). These reactions are catalyzed by cytoplasmic sulfotransferases. Substrates for sulfate conjugation include acetaminophen, morphine, ascorbic acid and endogenous compounds like chondroitin, heparin and some steroid hormones. The pool of available sulfates may become saturated in drug overdoses.

Drugs with amine and hydrazine groups, such as sulfonamides, are often conjugated to acetate (Sturgill and Lambert, 1997; Brown, 2001). N-acetyltransferase is a cytoplasmic enzyme involved in acetylation reactions.

Glutathione (GSH) and cysteine have sulfhydryl groups which readily bind many phase I metabolites (Brown, 2001). GSH, a free radical scavenger, prevents membrane damage from reactive metabolites in spontaneous reactions or with the selenium-dependent GSH peroxidases as a catalyst. Because these enzymes are cytosolic, damaged membrane phospholipids must be released by phospholipase A2 for detoxification. GSH is also involved in reduction and recycling of other antioxidants such as vitamins E and C (Dahm and Jones, 1996). When oxidized, GSH forms a dimer which must be reduced by NADPH-dependent GSH reductases. GSH becomes depleted in the fasting or overdosed patient (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Pineiro-Carrero and Pineiro, 2004). N-acetylcysteine is used to replenish GSH.

Significant species differences exist in phase II enzymes. UDP-glucuronosyltransferase is deficient in cats, affecting their ability to detoxify numerous compounds including acetaminophen (Court and Greenblatt, 1997; Brown, 2001). The Gunn rat, a mutant strain of Wistar rat, is also deficient in UDP-glucuronosyltransferase enzyme. Ferrets also have less capability to glucuronidate (Court, 2001). Swine have reduced sulfate conjugation abilities (Brown, 2001). Dogs do not have the ability to acetylate aromatic groups, which may interfere with their ability to metabolize sulfonamide antimicrobials (Brown, 2001; Trepanier, 2004).

Reactive metabolites of phase I act as free radicals, substances with unpaired electrons. Free radicals generate reactive oxygen species such as superoxide ( $O_2^{\bullet-}$ ), hydroxyl radicals ( $\bullet OH$ ) and hydrogen peroxide ( $H_2O_2$ ) through interactions with other molecules. Free radicals reacting with phospholipids of the plasma membrane, endoplasmic reticulum membrane or mitochondrial membranes cause a self-propagating chain reaction leading, eventually, to cell death (Dahm and Jones, 1996; Watkins, 1999).

Epoxides and other electrophiles are molecules with electron seeking properties. These form covalent bonds with nucleophilic molecules, for example by binding thiol groups on proteins (Dahm and Jones, 1996; Watkins, 1999; Zimmerman, 1999). Electrophiles produced by phase I reactions cause cell death by damage to critical proteins such as calcium transport proteins in membranes. Aflatoxin  $B_1$  binds to guanine residues in the DNA, leading to defects in protein transcription, resulting in carcinogenesis or cell death.

Aromatic amines and NSAIDs are examples where phase II reaction can form reactive metabolites, as mentioned previously. Glucuronidation of N-hydroxyaromatic amines, metabolites of aromatic amines, lead to formation of highly electrophilic aromatic nitrenium ions that can bind to DNA and other macromolecules, leading to bladder cancer. Several drugs including NSAIDs can form acyl-glucuronides, reactive intermediates, which bind to proteins to form adducts.

In addition to phase I and II biotransformation enzymes, studies suggest the involvement of hepatic transporter systems in drug efflux from hepatocytes as a means for the liver to rid itself of foreign chemicals. These are called the phase III transporter systems. Several transporter families mediating uptake of chemicals into liver and excretion of chemicals from liver into blood and/or bile have been identified. Generally, the organic anion transporting polypeptide family (OATPS), organic cation transporter 1 (OCT1) and organic anion transporter 2, mediate uptake of a large number of xenobiotics from the blood to the liver. Conversely, multidrug resistance proteins (MDRS), multidrug resistance associated proteins (MRPS) and breast cancer resistance

protein (BCRP) mediate efflux of xenobiotics from liver into bile or blood (Klaassen and Slitt, 2005). Similarly to phase I and II enzymes, these transporters can be induced or inhibited by drugs that are ligands of various nuclear receptors, such as aryl hydrocarbon receptor (AhR), constitutive androstane receptor (CAR) and pregnane x receptor (PXR).

## Inflammation

Inflammatory reaction represented by activation of resident Kupffer cells, natural killer and natural killer T cells and migration of activated neutrophils, lymphocytes and monocytes in the damaged liver region is a very common characteristic of toxin-induced hepatotoxicity. Although the main role of this inflammatory response is to remove dead and damaged cells, it can also aggravate the injury by releasing or forming cytotoxic, pro- and anti-inflammatory mediators (Jaeschke, 2008).

Upon activation, Kupffer cells generate reactive oxygen species (ROS), such as hydrogen peroxide, by the action of NADPH oxidase. These ROS will diffuse into neighboring hepatocytes, pose oxidative stress and lead to cell injury. It has also recently been found that intracellular proteins such as high-mobility group protein 1 (HMGB-1) are released by cells during necrosis, bind to toll-like receptors on Kupffer cells, which induces the synthesis and release of cytokines and chemokines (such as  $TNF-\alpha$ , IL-1). This leads to recruitment of cytotoxic neutrophil which can directly cause apoptotic cell death or generate ROS, such as hypochlorous acid, by the actions of NADPH oxidase and myeloperoxidase, and lead to cell injury (Jaeschke, 2008).

The role of Kupffer cells in toxicant-induced liver injury has been suggested by a variety of chemicals such as ethanol, acetaminophen,  $CCl_4$  and 1,2-dichlorobenzene. Involvements of neutrophils have been shown with hepatotoxicity associated with alpha-naphthylisothiocyanate and halothane. Although many compounds such as ethanol, allyl alcohol, aflatoxin  $B_1$ , monocrotaline, ranitidine and diclofenac are capable of causing liver injury without the involvement of neutrophils, inflammatory response initiated by endotoxin triggers a neutrophil-induced injury or aggravates the existing injury.

## TYPES OF TOXICANT-INDUCED LIVER INJURY

### Cell death

Necrosis is the predominant form of cell death in most toxic insults. Microscopically visible degenerative

changes to the hepatocyte may precede necrosis, including ballooning degeneration, hyaline degeneration and the presence of Mallory bodies (Zimmerman, 1999). Cells lose osmotic homeostasis and swell, which is visible on light microscopy. Swelling of organelles is seen on an ultrastructural basis (Dahm and Jones, 1996; Treinen-Moslen, 2001). Energy production fails due to loss of calcium homeostasis (Dahm and Jones, 1996; Zimmerman, 1999). Eventually there is rupture of the cell membrane and leakage of cell contents. Typically, necrosis results in elevation of serum transaminases such as alanine transaminase, aspartate transaminase and sorbitol dehydrogenase. Depending on the extent of liver necrosis, liver function may or may not be affected.

Necrosis is often initiated by damage to membranes, either the plasma membrane of the cell or the membranes of organelles, particularly the mitochondria, such as with acetaminophen toxicosis. Cell membrane damage can be caused by peroxidation of membrane phospholipids, such as with carbon tetrachloride. Damage to the plasma membrane interferes with ion regulation, damage to the membranes of the mitochondria interferes with calcium homeostasis and energy production, and damage to the smooth endoplasmic reticulum membrane diminishes the ability of that organelle to sequester calcium (Zimmerman, 1999). Inhibition of protein synthesis is an alternate mechanism of cell necrosis. Toxins that act in this way include phalloidin and related mushroom toxins, which inhibit the action of RNA polymerase and therefore mRNA synthesis (Pineiro-Carrero and Pineiro, 2004).

Necrotic liver injury can be focal, zonal, bridging or massive and panlobular. Focal necrosis is randomly distributed and involves hepatocytes individually or in small clusters (Treinen-Moslen, 2001). Zonal necrosis is common and usually occurs in zone 3, the centrilobular area (Zimmerman, 1999; Treinen-Moslen, 2001; Plumlee, 2004) due to higher levels of phase I enzymes in this region. Grossly, the liver will have a reticulated pattern with dark red central areas separated by brown to yellow areas. Bridging necrosis describes confluent zones of necrosis that extend between zones of the lobule and between lobules (Treinen-Moslen, 2001). Panlobular or massive necrosis denotes hepatocyte loss throughout the lobule with loss of lobular architecture. The liver is grossly swollen and friable with panlobular injury.

Apoptotic cells undergo cell shrinkage, nuclear condensation and pyknosis (Dahm and Jones, 1996; Treinen-Moslen, 2001), but mitochondrial function (Pineiro-Carrero and Pineiro, 2004) is maintained and the cell membrane remains intact (Zimmerman, 1999). This type of cell death is not associated with inflammation. Although apoptosis, sometimes termed "programmed cell death," is a normal physiological process, it may be induced by xenobiotics due to oxidative stress, decrease

in apoptotic suppressors or enhanced expression of apoptosis genes. Apoptotic cells are occasionally seen in the centrilobular area but are rapidly phagocytized by macrophages and other hepatocytes.

Although necrosis and apoptosis are considered separate entities, an alternate view is emerging that apoptosis and necrosis are frequently the consequence of the same initiating factors and signaling pathways. Rather than being separate entities, apoptosis and necrosis in their pure form may represent extremes on a continuum of cell death. Thus necrosis resulting from oncosis is termed "oncotic necrosis" and that originating from apoptosis is termed "apoptotic necrosis" (Levin *et al.*, 1999; Jaeschke *et al.*, 2004; Malhi *et al.*, 2006).

The nature of the lesions can tell us something about the mechanism of injury. Several drugs/chemicals such as carbon tetrachloride (CCl<sub>4</sub>), acetaminophen, thioacetamide, allyl alcohol and ethanol result in hepatocyte oncotic necrosis. Centrilobular necrosis is a common pattern and is seen with carbon tetrachloride, acetaminophen and thioacetamide. Hypoxia also causes centrilobular necrosis since this region, or zone 3, has lowest levels of oxygen, as mentioned previously.

Less commonly, a midzonal pattern is seen in endotoxin-mediated hepatitis in a rat model (Ramaiah *et al.*, 2004). Necrosis of periportal hepatocytes can be observed, although rare, with compounds such as allyl alcohol. Hepatocytes in this region are usually young cells and necrosis often leads to portal fibrosis. Bile duct proliferation may also follow. Ethanol ingestion produces multifocal, random hepatic necrosis.

Necrosis may be a primary event caused by reactive intermediates (e.g., acetaminophen, thioacetamide and carbon tetrachloride) or may be a secondary event following infiltration of inflammatory cells as seen with ethanol.

## Hepatic steatosis

Hepatic steatosis/lipidosis or fatty liver is simply the accumulation of fat vacuoles within hepatocytes. Steatosis is a common response to a variety of hepatotoxins and represents a potentially reversible hepatocyte injury (Treinen-Moslen, 2001). Grossly, the affected liver will be swollen with rounded edges, friable and light brown to yellow in color. Due to the fat accumulation, sections of the affected liver will float in formalin (Plumlee, 2004). Compounds that produce prominent steatosis associated with mortality include the antiepileptic drug valproic acid and the antiviral agent fialuridine. Other toxins that may cause hepatic steatosis include aflatoxin, white or yellow phosphorus, ethanol and carbon tetrachloride.

Although steatosis has been considered a benign and reversible change, studies have determined association

to biochemical alterations that produce steatohepatitis, fibrosis and cirrhosis (Ramaiah *et al.*, 2004). Non-alcoholic fatty liver disease (NAFLD), a syndrome associated with obesity in humans, who are often type II diabetics, has a marked inflammatory component (Diehl, 2002). Several endocrine abnormalities also result in steatosis, making determination of a cause challenging. Serum transaminase concentrations in patients with steatosis are variable and often include a mild to moderate increase in serum transaminase. Cholestasis occurs with marked lipid accumulation.

Steatosis is termed microvesicular if fat vacuoles are small and do not displace the nucleus. Microvesicular steatosis is often associated with slow lipid accumulation (Bastianello *et al.*, 1987; Plumlee, 2004). This form of steatosis may indicate deficiency in mitochondrial  $\beta$ -oxidation of fatty acids. It is a relatively severe form of steatosis and has been seen in primates and dogs with aflatoxicosis (Bastianello *et al.*, 1987; Zimmerman, 1999) and people with valproic acid toxicosis (Sturgill and Lambert, 1997; Zimmerman, 1999).

Macrovesicular steatosis, more common in domestic animals, describes hepatocytes containing one, or occasionally a few, large fat vacuoles that displace the nucleus to the periphery of the cytoplasm (Plumlee, 2004). Macrovesicular steatosis indicates an imbalance between fatty acid uptake and secretion of very low density lipoproteins due to increased triglyceride mobilization, decreased fatty acid oxidation, decreased synthesis of very low density lipoproteins or other metabolic anomalies (Sturgill and Lambert, 1997; Zimmerman, 1999; Treinen-Moslen, 2001; Plumlee, 2004). Macrovesicular steatosis has been reported in dogs with subacute aflatoxicosis (Bastianello *et al.*, 1987). Zone 1 macrovesicular steatosis is reported with yellow phosphorus toxicosis (Zimmerman, 1999). Macrovesicular steatosis occurs with a variety of metabolic disease in domestic animals, particularly in obese cats with anorexia and preparturient cattle due to mobilization of lipids.

## Steatohepatitis

Steatohepatitis is usually the next stage of steatosis if untreated (Lieber, 1994; Bautista, 2002; French, 2003). Steatohepatitis is the accumulation of lipid and the presence of inflammatory cells within hepatic parenchyma. The inflammatory cells involved are usually neutrophils and mononuclear leukocytes. There is no specificity noted with this pathologic stage and the distribution of lipidosis and inflammation is random and multifocal. Conditions usually associated with steatohepatitis are alcoholic liver disease, NAFLD and endotoxemia secondary to intestinal disease. Any toxic compounds that cause steatosis can also result in steatohepatitis if the

condition is left untreated. It should also be noted that steatohepatitis in humans may progress to fibrosis/cirrhosis and hepatocellular carcinoma if the inciting cause is not removed or treated (Diehl, 2002). The clinical biochemistry alterations of the liver usually include elevated serum transaminases.

## Hepatic fibrosis

Fibrosis is a nonspecific lesion which usually results from chronic inflammation. Chronic inflammation can be the result of continuous exposure to a variety of hepatotoxic chemicals such as organic arsenicals, vinyl chloride or high doses of vitamin A (Zimmerman, 1999), chronic ethanol ingestion and non-alcoholic fatty liver disease. Fibrosis usually occurs around the portal area, in the space of Disse, and around the central veins. The hepatocytes are replaced with fibrous material and thus there is hepatocyte loss. Periportal fibrosis may lead to portal hypertension.

## Cirrhosis

Hepatic cirrhosis is end stage liver disease. Cirrhosis describes irreversible changes characterized by accumulation of excessive collagen deposition in the form of bridging fibrosis, disrupting hepatic architecture. Entrapped hepatocytes undergo random mitosis and growth, termed nodular regeneration. Cirrhosis may be micronodular or macronodular, depending on the amount of fibrosis and tissue regeneration. A liver with micronodular fibrosis has a grossly cobblestoned surface and is firm and difficult to cut with a knife.

The serum concentration of transaminase enzymes is low at this stage due to the lack of functional hepatocytes. Liver function parameters such as bile acids and ammonia are markedly elevated. Prognosis for recovery is poor. Physicians resort to liver transplantation as the only solution to restore adequate liver function in human patients.

Investigations of animals dosed with ethanol for one to several months have shown that the mechanisms of liver injury are numerous, indicating a complex, multifactorial pathogenesis for alcoholic liver disease, as seen in Figure 17.2 (Lieber, 1994). The roles of CYP2E1, fatty acid metabolism, oxidative damage, endotoxin, Kupffer cell and neutrophil infiltration have been extensively investigated (Di Luzio, 1966; Bardag-Gorce *et al.*, 2000; Kono *et al.*, 2000; Hoek and Pastorino, 2002). Progression of liver disease correlates well with the dose of ethanol consumed daily and the duration of alcohol consumption. Alcoholic hepatic steatosis, steatohepatitis, fibrosis and cirrhosis represent a sequential progression in

**FIGURE 17.2** Progression of alcoholic liver disease. Consumption of ethanol produces hepatic pathology in a sequence ranging from steatosis (fatty liver) on one extreme to fibrosis/cirrhosis on the opposite end of the spectrum. Steatosis and steatohepatitis represent acute stages of alcoholic liver disease. ROS = reactive oxygen species; RNS = reactive nitrogen species.

alcoholic liver disease. Females are more sensitive than males and experience a higher incidence of liver injury (Apte *et al.*, 2005). Inflammation is predominantly neutrophilic within regions of necrosis and Mallory body formation. Although many of these changes have been observed in experimental models of alcoholic hepatitis, progression to cirrhosis has rarely been experimentally reproduced.

### Pigment accumulation

Various substances can accumulate within hepatocytes or Kupffer cells and are often microscopically visible as pigment. Occasionally, these pigments lend a grossly visible tint to the liver. If there is damage to the biliary tract, by cholestasis or biliary obstruction, bile pigment can accumulate in canaliculi and bile ducts, producing a grossly yellow to green color (Zimmerman, 1999; Plumlee, 2004). If there is a bile canaliculus rupture, yellow pigment can be seen in hepatocytes and Kupffer cells.

Iron in the form of hemosiderin is stored in the liver as a yellow-brown pigment, which is better visualized using Pearl's Prussian blue (Plumlee, 2004). Copper is yellow-brown and is visualized using rhodanese. These accumulations of copper and iron can be released by the hepatocytes through necrosis. The newly regenerated hepatocytes may not have excessive levels and may show little pigment accumulation, thus copper toxicosis should be confirmed with kidney copper levels in such cases.

Lipofuscin can be present as a yellow-brown pigment within hepatocytic lysosomes as a senile change and as a result of cells being unable to break down old and damaged organelles in the cytosols (Plumlee, 2004). Melanin pigments can also be present in the liver hepatocytes,

Kupffer cells and the portal connective tissue without any disease or toxic insults. Differentiation of some of these pigments may be difficult histologically but can be easily done by use of special stains as mentioned above.

### Hepatic neoplasia

Chemically induced tumors can originate from hepatocytes, biliary epithelium and very rarely from sinusoidal endothelium. Neoplasms occur months or years after toxin exposure (Plumlee, 2004). If a toxin produces direct damage to DNA, a single exposure may lead eventually to neoplastic changes (Zimmerman, 1999; Pineiro-Carrero and Pineiro, 2004). Aflatoxin B<sub>1</sub> is an agent that acts by alkylating DNA and is associated with hepatocellular carcinoma in humans infected with hepatitis B virus. Aflatoxin B<sub>1</sub> has also been implicated in liver cancers in trout and laboratory animals (Newberne and Butler, 1969). Nongenotoxic agents must be given at high doses for long periods of time to induce cancer. Examples of nongenotoxic agents include phthalate esters in plasticizers, phenoxy acid herbicides and hypolipidemic drugs.

Hepatic adenomata are benign hepatocytic neoplasms associated with contraceptive steroid use in humans (Zimmerman, 1999). Hepatocellular carcinomata are malignant neoplasms induced by various chemicals and botanical toxins and are of more concern. They have been found in humans affected with hepatitis B virus and exposed to aflatoxin B<sub>1</sub>, as noted above, and associated with anabolic steroid abuse. Other risk factors include viral hepatitis C and D, ethanol abuse and exposure to microcystin.

Biliary carcinomata or cholangiocarcinomata are uncommonly associated with exposure to drugs/chemicals. Biochemical indicators of note include normal, elevated or low concentrations of serum transaminases, loss of liver function and the resulting increase in bile acid and ammonia concentrations.

Angiosarcomata or hemangiosarcomata derive from sinusoidal epithelium (Zimmerman, 1999; Treinen-Moslen, 2001; Plumlee, 2004). These neoplasms are rare but rapidly lethal and have been associated with exposure to vinyl chloride, inorganic arsenics and Thorotrast, a form of radioactive thorium dioxide once used in radiographic contrast studies.

### Megalocytosis

Hepatic megalocytosis can be observed in some aged animals but is also characteristic lesions observed by toxic insults, namely pyrrolizidine alkaloids and aflatoxins. It is caused by impaired cell division, and results

in enlarged hepatocytes with markedly enlarged nuclei (Plumlee, 2004). Pyrrolizidine alkaloids have an anti-mitotic effect on the hepatocytes without the inhibition of DNA synthesis. Since it is a natural urge for hepatocytes to proliferate to replace the damaged liver, hepatocytes become active in DNA and protein synthesis; however, they cannot divide and result in megalocytosis. Very often, chronic pyrrolizidine intoxication is accompanied by hepatic fibrosis as well as biliary hyperplasia and sometimes nodular regeneration of parenchyma.

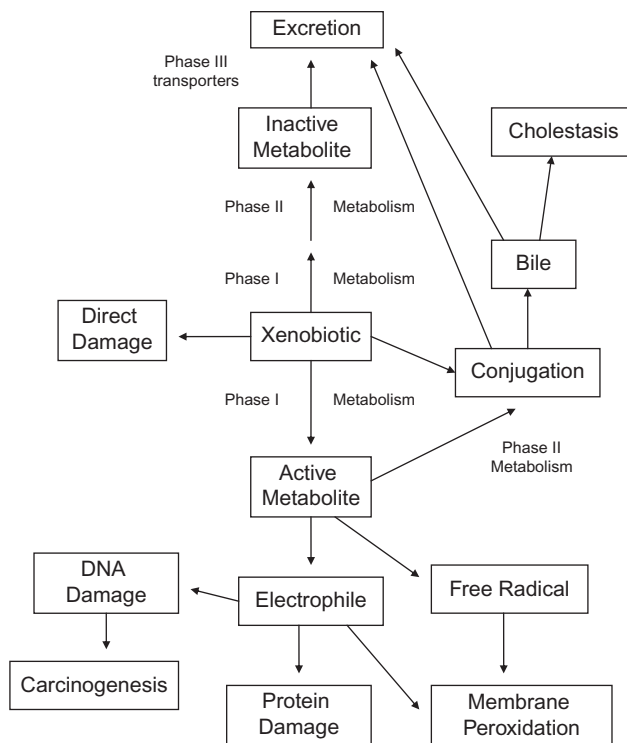

## MECHANISMS OF LIVER DAMAGE

Mechanisms of liver injury have been classified as either intrinsic or idiosyncratic. Intrinsic injury can produce steatosis, necrosis, cholestasis or a multiple of these lesions, often with minimal inflammation (Sturgill and Lambert, 1997). Intrinsic liver injury is a predictable, reproducible, dose-dependent response to a xenobiotic (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Zimmerman, 1999; Pineiro-Carrero and Pineiro, 2004). A threshold dose exists for xenobiotics causing intrinsic liver injury and there is often a predictable latent period between the time of exposure and clinical evidence of liver injury. Intrinsic liver injury accounts for the vast majority of toxic liver injury cases and is often produced by reactive products of xenobiotic metabolism such as electrophiles or free radicals, though a few drugs cause intrinsic liver injury without bioactivation. An abbreviated summary of mechanisms of intrinsic liver injury is illustrated in Figure 17.3.

Idiosyncratic responses are, by contrast, unpredictable responses to a drug or other xenobiotic. They are rare, non-dose dependent and often associated with extrahepatic lesions (Sturgill and Lambert, 1997; Zimmerman, 1999; Pineiro-Carrero and Pineiro, 2004; Shenton *et al.*, 2004). Extrahepatic clinical signs may include pyrexia, rash and peripheral eosinophilia. Some idiosyncratic drug reactions resemble serum sickness. Hepatic changes associated with idiosyncratic drug reactions include necrosis, cholestasis or both, and there is often an inflammatory response involving macrophages and eosinophils.

### Oxidative stress mediated by free radicals

Free radicals are generated from within hepatocytes through a variety of mechanisms: ionizing radiation, oxidative metabolism by cytochrome P450s, reduction and oxidation (redox) reactions that occur during normal metabolism, transition metals such as iron and copper, and nitric oxide generated by a variety of inflammatory

**FIGURE 17.3** Basic mechanisms of hepatic injury showing the relationship between multiple pathways for metabolism and toxicity for any compound. The liver metabolizes xenobiotics (and some endogenous compounds) to form water soluble products appropriate for urinary or biliary excretion. Some compounds are activated through these metabolic processes to free radicals, electrophiles or other toxic products that may induce hepatic injury.

cells. The reactive species generated result in lipid peroxidation of membranes, oxidative modification of proteins and DNA disruption (Crawford, 1999).

Free radicals have unpaired electrons, making them highly reactive. They may be formed by one electron oxidation and reduction reactions, producing cationic and anionic radicals, respectively (Dahm and Jones, 1996). Alternately, homolytic bond scission produces neutral radical formation. The free radical nitric oxide ( $\bullet\text{NO}$ ), an important cell signaling agent released by leukocytes, reacts with superoxide to form peroxynitrite. Hydroxyl radicals, superoxide radicals and hydrogen peroxide are major reactive oxygen species (ROS).

Free radicals produce peroxidation of phospholipids within the cell plasma membrane and in membranes of mitochondria and endoplasmic reticulum. The radicals remove a proton ( $\text{H}^+$ ) from a methylene carbon within a polyunsaturated fatty acid, forming a lipid-free radical. This step is called *initiation*. This lipid-free radical then abstracts a proton from a neighboring polyunsaturated fatty acid, generating more lipid-free radicals. *Propagation* by this mechanism is estimated to occur 4 to 10 times per initiation. The effects of lipid peroxy

**FIGURE 17.4** Metabolism and mechanism of acetaminophen toxicity. Bioactivation of acetaminophen by P450 enzymes results in the formation of the reactive intermediate (NAPQI) which forms covalent adducts with glutathione which is then converted to mercapturic acid. When the amount of the reactive metabolite formed exceeds the glutathione available for binding, the excess metabolite binds to tissue molecules, forming covalent adducts, resulting in centrilobular hepatic necrosis.

radicals on the cell membrane include: increased permeability, decreased fluidity, inactivation of membrane proteins (Dahm and Jones, 1996) and, in the case of mitochondrial membranes, loss of polarity (Watkins, 1999). Lipid peroxy radicals react with metal ions stored within the hepatocyte to generate more lipid radicals.

The most frequent mechanism of free radical production associated with hepatocellular injury is bioactivation of xenobiotics by the cytochrome P450 system. Phase I metabolism activates substrates to reactive intermediate molecules in preparation for phase II conjugation reactions. However, in circumstances of high exposure, phase I products accumulate. Lesions produced by these compounds tend to be centrilobular due to the centrilobular location of the cytochrome P450s responsible for metabolism.

A classical example of phase I bioactivation is cell death resulting from acetaminophen (Figure 17.4). Acetaminophen is a widely used analgesic that rarely induces clinical signs at therapeutic doses, except in particularly susceptible feline species, where metabolites of acetaminophen produce acute liver failure and oxidation of hemoglobin to methemoglobinemia. The details of acetaminophen toxicity are described in another chapter in this book on over-the-counter drugs, but the unstable intermediate metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI), is known to be the cause of hepatocyte injury.

The reaction that produces NAPQI generates superoxide anions as a by-product. NAPQI itself also acts as an electrophile, targeting mitochondria in particular, forming covalent adducts with protein thiol groups and other cellular macromolecules. Interaction of NAPQI with other cellular molecules also generates reactive oxygen species, leading to oxidative stress on the hepatocyte (Dahm and Jones, 1996; Zimmerman, 1999). Plasma membrane proteins involved in calcium homeostasis and

**FIGURE 17.5** Metabolism and mechanism of carbon tetrachloride toxicity. Carbon tetrachloride metabolism by CYP450 leads to free radicals such as trichlorocarbon and trichloroperoxy radical that initiate lipid peroxidation. The centrilobular location of CYP2E1 enzyme is mainly responsible for carbon tetrachloride metabolism and contributes to centrilobular necrosis similar to acetaminophen toxicity.

adenine nucleotides are other targets (Dahm and Jones, 1996; Sturgill and Lambert, 1997). The role of calcium and Kupffer cell activation have been implicated as contributing factors for acetaminophen-induced liver injury through the production of reactive nitrogen species (Treinen-Moslen, 2001).

Another classic example of xenobiotic bioactivation, generation of free radicals, leading to peroxidation, is conversion of carbon tetrachloride (CCl<sub>4</sub>) into trichlorocarbon radical (•CCl<sub>3</sub>) and then to trichloroperoxy radical (CCl<sub>3</sub>OO•) (Figure 17.5). The main phase I enzyme involved in bioactivation of both aforementioned acetaminophen and CCl<sub>4</sub> is CYP2E1, which is induced by alcohol consumption. Lipid peroxidation caused by free radicals increases the Ca<sup>2+</sup> permeability of the plasma membrane and leads to disruption of calcium homeostasis and centrilobular cell necrosis. In addition, •CCl<sub>3</sub> can directly bind to tissue macromolecules and lipid peroxy radicals can also form protein adducts (Jaeschke, 2008).

### Disruption of calcium homeostasis and cell membrane damage

Calcium ions (Ca<sup>2+</sup>) are important for the mediation of hepatocellular injury. Cytosolic-free calcium is maintained at relatively low concentrations compared to the extracellular concentrations. The majority of intracellular calcium is sequestered within the mitochondria and endoplasmic reticulum. Membrane-associated calcium and magnesium ATPases are responsible for maintaining this calcium gradient (Farrell *et al.*, 1990).

Disruption or changes in the permeability of the plasma membrane, mitochondrial membranes and

membranes of the smooth endoplasmic reticulum can lead to significant and persistent increases in the intracellular calcium. Depletion of available NADPH leads to calcium release, since calcium pumps in the mitochondrial membrane require NADPH (Cullen, 2005).

Excessive cytoplasmic calcium ions activate a variety of enzymes with further membrane damaging effects, including ATPases, phospholipases, proteases and endonucleases. Thus increased calcium causes increased mitochondrial membrane permeability and induction of apoptosis and necrosis. Calcium is required for cytoskeletal maintenance and function as well (Dahm and Jones, 1996; Delgado-Coello *et al.*, 2006). Increased calcium ions may also stimulate release of cytokines and eicosanoids by the Kupffer cells. Chemicals that cause liver damage by this mechanism include carbon tetrachloride, quinines, peroxides, acetaminophen, iron and cadmium.

### Mitochondrial injury

Mitochondria function in the production of energy, in the form of ATP, for cellular function by the process of oxidative phosphorylation. Hepatocytes are highly metabolically active and thus require a continuous supply of ATP. Hepatocytes active in detoxification or replication and replacement of damaged tissue have a still higher ATP requirement (Dahm and Jones, 1996). Compounds that disrupt mitochondrial oxidative phosphorylation include bile acids and amiodarone. Mitochondria are critical to modulation of cell redox status, osmotic regulation, pH control, cytosolic calcium homeostasis and cell signaling, and mitochondrial DNA is more susceptible to oxidant damage than nuclear DNA (Stirnemann *et al.*, 2010). Mitochondria are targets for virtually all types of injurious stimuli, including hypoxia and toxins including oxidants, electrophiles, lipophilic cations and weak acids. Damage is often precipitated by increases in cytosolic calcium.

Hepatic injury is frequently accompanied by morphological mitochondrial changes. These structural abnormalities include greatly increased size and the development of crystalline inclusions and are regarded as pathologic, reflecting either protective or degenerative responses to injury. Mitochondrial damage results in formation of high conductance channels, the so-called mitochondrial permeability transition, in the inner mitochondrial membrane. This is an irreversible change and, because membrane potential is critical for mitochondrial oxidative phosphorylation, constitutes a deathblow to the cell.

Oxidative phosphorylation produces reactive oxygen species which are deactivated within the mitochondria by antioxidants (Watkins, 1999). Glutathione within mitochondria functions as a scavenger for peroxides and

electrophiles. Synthesis of glutathione takes place within the cytosol and requires ATP. Greater than 90% depletion in the glutathione reserve decreases the ability of the mitochondrion to detoxify reactive oxygen species associated with ATP production (Watkins, 1999). Glutathione S-transferase, the enzyme required for recycling of glutathione, is sometimes overwhelmed by xenobiotics and reactive metabolites (Dahm and Jones, 1996).

Xenobiotics can cause cell death by their effects on mitochondrial DNA. Some antiviral deoxynucleoside analogs disrupt mitochondrial DNA synthesis through the inhibition of DNA polymerase gamma, thus depleting mitochondria, resulting in hepatocyte death.

Chemicals that damage mitochondrial structure, enzymes or DNA synthesis can disrupt beta oxidation of lipids and oxidative energy production within hepatocytes, which, if prolonged, leads to microvesicular steatosis which can progress to macrovesicular steatosis. This sequence of events is seen in alcoholic and non-alcoholic steatohepatitis. The role of mitochondria has been extensively studied with non-alcoholic fatty liver disease in people. Alcoholic steatosis and other forms of hepatic steatosis have been linked to impairment of ATP homeostasis and mitochondrial abnormalities have been reported in a growing body of literature. Aspirin, valproic acid and tetracyclines are also known to inhibit beta oxidation of fatty acids in mitochondria leading to lipid accumulation.

### Disruption of cytoskeleton

Changes in intracellular calcium homeostasis produced by active metabolites of xenobiotics may cause disruption of the dynamic cytoskeleton. There are a few toxins that cause disruption of the cytoskeleton through mechanisms independent of biotransformation. Microcystin is one of these toxins. Microcystin is produced by the cyanobacterium *Microcystis aeruginosa*. Similar toxins are produced by other species of cyanobacteria. The hepatocyte is the specific target of microcystin, which enters the cell through a bile-acid transporter. Microcystin covalently binds to serine/threonine protein phosphatase, leading to the hyperphosphorylation of cytoskeletal proteins and deformation of the cytoskeleton (Treinen-Moslen, 2001).

Phalloidin and related toxins found in some mushrooms, including *Amanita phalloides*, act by binding tightly to actin filaments and preventing cytoskeletal disassembly (Treinen-Moslen, 2001).

### Cholestasis

Cholestasis can be transient or chronic (Treinen-Moslen, 2001). If severe, bile pigments make the liver

appear grossly yellow to yellow-green (Plumlee, 2004). Cholestasis is subdivided into canalicular cholestasis and cholangiodestructive cholestasis.

Canalicular cholestasis can be produced by drugs/chemicals that damage the structure and function of bile canaliculi. A key component of bile secretion involves several ATP-dependent export pumps, such as the canalicular bile salt transporter that moves bile salts, and other transporters that export bile constituents from the hepatocyte cytoplasm to the lumen of the canaliculus. Some drugs bind these transporter molecules, arresting bile formation and movement within the canalicular lumen (Klaassen and Slitt, 2005). Secondary bile injury results if there is cholestasis due to the detergent action of bile salts on the biliary epithelium or hepatocytes in areas of cholestasis.

Cholestasis can also occur simply as a result of physical obstruction of canaliculi within the liver parenchyma (intrahepatic) or outside the liver (extrahepatic). Causes of cholestasis include hepatobiliary tumors, endotoxemia, hepatocyte swelling and intraductal crystals such as calcium salts of plant saponins, for example those found in *Tribulus* spp. Most chemicals that cause cholestasis are excreted in the bile, including the mycotoxin sporidesmin, which concentrates 100-fold in the bile (Treinen-Moslen, 2001).

Disruption of actin filaments within the hepatocyte causes cholestasis by preventing the normal pulsatile contractions that move bile through the canalicular system to the bile ducts. Drugs that bind to actin filaments, such as phalloidin, those that affect cytoskeletal assembly, such as microcystin, and those that affect calcium homeostasis and cellular energy production generate this type of injury. Cholestatic disorders typically result in elevated serum alkaline phosphatase, gamma glutamyltransferase and serum bilirubin.

Cholangiodestructive cholestasis is caused by intrahepatic or extrahepatic bile duct obstruction. Injury of biliary epithelium leads to cell edema, sloughing into the lumen and inflammation, contributing to obstruction (Treinen-Moslen, 2001; Plumlee, 2004). Chronic lesions of cholangiodestructive cholestasis typically include bile duct proliferation and periductular fibrosis. Vanishing bile duct syndrome, characterized by a loss of bile ducts, has been described in chronic cholestatic disease in humans (Zimmerman, 1999; Treinen-Moslen, 2001) and produced experimentally in dogs (Uchida *et al.*, 1989).

## Hepatogenous photosensitization

Cholestatic diseases in herbivores, ruminants in particular, are associated with dermal photosensitization. The presentation of photosensitization is similar to that of sunburn, but with a more rapid onset and associated

with different wavelengths of light (Rowe, 1989). Photosensitization is caused by circulation of photoactive compounds. Primary photosensitization involves ingestion or dermal absorption of a photodynamic compound which enters the circulation, such as hypericin from *Hypericum perforatum* or St. John's wort, and is described elsewhere in this book. The second type of photosensitization is hepatogenous photosensitization, which is discussed in detail in this chapter.

Hepatogenous photosensitization usually occurs secondary to cholestasis. Herbivores ingest large quantities of chlorophyll. Metabolism of chlorophyll by bacteria in the gastrointestinal tract produces phylloerythrin, a photoactive compound, which, after absorption, is predominantly excreted in the bile (Rowe, 1989; Burrows and Tyrl, 2001). Cholestasis will prevent excretion of this photoactive compound. Upon exposure to light of wavelengths 320 to 400nm, circulating phylloerythrin contributes to generation of singlet oxygen, causing lipid peroxidation in areas of skin unprotected by hair or melanin (Burrows and Tyrl, 2001). Not all causes of cholestasis produce photosensitization, thus icterus may occur in the absence of photosensitization (Rowe, 1989).

Hepatocyte swelling may produce cholestasis. Agents that may cause photosensitization through hepatocyte damage include the toxic plant *Lantana camara* which causes steatosis. Plants containing pyrrolizidine alkaloids (such as *Senecio*, *Crotalaria*, *Cynoglossum* spp., *Tetradymia* spp., *Trifolium hybridum*, *Artemisia nigra*) also causes secondary photosensitization. Because significant hepatocyte damage must occur before the individual presents with photosensitization, and damage of this type usually carries a poor prognosis (Rowe, 1989).

Agents that damage bile ducts include the mycotoxin sporidesmin and saponogenins from the plant *Tribulusterrestris*. Sporidesmin, produced by *Pithomyces chartarum* which grows predominantly on ryegrass pastures in Australia and New Zealand, acts by directly damaging biliary epithelium, producing cell necrosis and degeneration. Bile ducts become occluded with cell debris and inspissated bile. Consequent periductular fibrosis also further occludes bile ducts (Rowe, 1989).

Several plant species cause bile stasis through precipitation of calcium salts of sapogenic glucuronides within bile ducts. The major toxic saponogenins from *T. terrestris* are diosgenin and yamogenin. These compounds are hydrolyzed in the gastrointestinal tract to sapogenins, which are further metabolized before glucuronidation in the liver (Burrows and Tyrl, 2001). Sapogenins directly occlude bile ducts and damage canalicular membranes. Note that while *T. terrestris* poisoning is reported with some frequency in South Africa and Australia, it is believed that the toxic sapogenins are either absent or present in much lower concentrations in *T. terrestris* growing in the United States (Burrows and Tyrl, 2001).

## Inhibition of tissue repair response

Tissue repair is a dynamic response, involving compensatory cell proliferation and tissue regeneration, which is stimulated in acute toxicosis to recover hepatic structure and function. Extensive evidence from rodent models using structurally and mechanistically diverse hepatotoxins such as acetaminophen, carbon tetrachloride, chloroform, thioacetamide, trichloroethylene and allyl alcohol have demonstrated that tissue repair plays a critical role in determining the final outcome of toxic insult, i.e., recovery from injury and survival or progression of injury leading to liver failure and death (Mehendale, 2005).

Thioacetamide, originally used as a fungicide, is potentially hepatotoxic after being bioactivated by cytochrome P450 and/or flavin-containing monooxygenase (FMO) systems to sulfinic (sulfoxide) and sulfenic (sulfone) metabolites, which cause centrilobular necrosis. Thioacetamide bioactivation is primarily mediated by the cytochrome P450 enzyme CYP2E1. Studies suggest that thioacetamidesulfoxide, a relatively stable intermediate of thioacetamide metabolism, is obligatory for the hepatotoxic effects, indicating that it is the penultimate reactive metabolite. Accordingly, it has been reported that the hepatotoxic effects of thioacetamide are only expressed after metabolic conversion to thioacetamide S-oxide, which undergoes further metabolism to an as yet unidentified metabolite, most likely the reactive unstable thioacetamidesulfone. The reactive metabolite of thioacetamide binds to liver proteins with the formation of acetylimidolysine derivatives that are responsible for thioacetamide-induced hepatotoxic effects. Progression of thioacetamide-induced liver injury has also been attributed to inhibition of tissue repair response based on studies of diet restriction (Ramaiah and Mehendale, 2000).

Tissue repair is a complex process governed by intricate cellular signaling involving chemokines, cytokines, growth factors and nuclear receptors, leading to promitogenic gene expression and cell division. Tissue repair encompasses regeneration of hepatocytes, hepatic extracellular matrix and angiogenesis, processes necessary to completely restore hepatic structure and function after injury. New insights have emerged over the last quarter century indicating that tissue repair follows a dose response: increasing xenobiotic dose, a threshold is reached beyond which repair is delayed or impaired through inhibition of cellular signaling. Runaway secondary events then cause tissue destruction, organ failure and death. Prompt and adequate tissue repair after toxic injury is critical for recovery. Tissue repair is modulated by species, strain, age, nutrition, disease condition and other factors, accounting for the marked differences in individual susceptibility and toxic outcome (Ramaiah *et al.*, 1998; Mehendale, 2005).

## IDIOSYNCRATIC REACTIONS

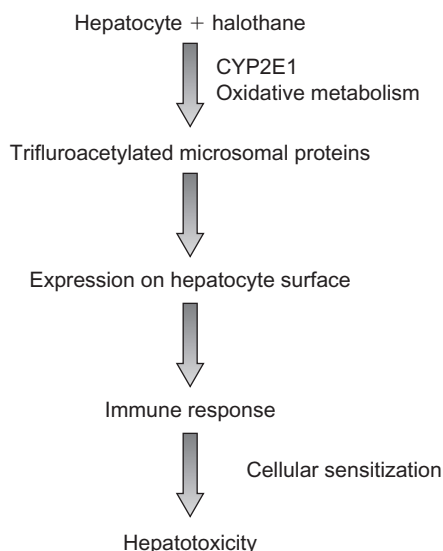

Idiosyncratic drug reactions often occur after sensitization followed by reexposure to a drug and are classified as immune-mediated idiosyncratic hepatotoxicity (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Zimmerman, 1999; Treinen-Moslen, 2001). A delay of 3 to 4 weeks after 1 to 2 week course of medication can be seen for these drugs (e.g., amoxicillin-clavulanic acid) before clinical signs become evident (Kaplowitz, 2001; Zimmerman, 1999), but onset is expedited with rechallenge (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Watkins, 1999).

Neoantigens may result from adducts formed by interaction of reactive drug metabolites with cellular proteins. These neoantigens could be processed by Kupffer cells or other antigen presenting cells, transported to the cell surface and presented to the immune system as antigens. Cell and antibody-mediated immune response can cause severe liver damage. Various drugs are believed to cause immune-mediated idiosyncratic reactions in humans, including halothane, diclofenac, phenytoin and sulfonamides (Sturgill and Lambert, 1997; Watkins, 1999; Zimmerman, 1999; Treinen-Moslen, 2001). The idiosyncratic reaction to halothane has been well studied (Figure 17.6).

Other idiosyncratic drug reactions can be seen after a very long latency (up to 12 months), but are usually not associated with features of hypersensitivity and have been variable in response to a rechallenge. These are classified as nonimmuno-mediated idiosyncratic reactions (Kaplowitz, 2001). Examples of drugs that are known to cause this type of idiosyncratic reaction include troglitazone, valproate, amiodarone, ketoconazole, disulfiram and isoniazid. However, some involvement of allergic mechanism cannot be completely rejected in these drugs, thus this classification should still be viewed as tentative (Kaplowitz, 2005).

Many drugs implicated in idiosyncratic liver injury are known to affect mitochondrial function (Stirnemann *et al.*, 2010). A proposed explanation for the delayed onset of clinical signs is that mitochondrial damage is not manifested until a threshold has been reached, then cell death occurs. Genetic polymorphisms in activation of detoxifying enzymes have been associated with increased susceptibility to idiosyncratic drug reactions in some people, further implicating the role of oxidative stress (Stirnemann *et al.*, 2010).

A few idiosyncratic drug reactions have been reported in veterinary medicine. The most well known is probably carprofen in dogs (MacPhail *et al.*, 1998). Carprofen is a nonsteroidal anti-inflammatory agent. Clinical signs of the idiosyncratic reaction to carprofen occur approximately 20 days following the first exposure to the drug and include anorexia, vomiting and icterus. Signs do not correlate with drug dose. Affected dogs have elevated

**FIGURE 17.6** Postulated mechanism of immune-mediated halothane hepatotoxicity. Halothane-mediated hepatitis is the best example for immune-mediated liver damage. Oxidative pathway yields trifluoroacetylchloride, which can react with microsomal proteins to form a neoantigen which then can generate immune response leading to hepatic injury.

alanine transaminase, aspartate transaminase, alkaline phosphates and serum total bilirubin. There is mild to severe bridging hepatocyte degeneration and necrosis with evidence of apoptosis. Mild to moderate periportal inflammation is reported. Spayed female dogs are over-represented among the affected (MacPhail *et al.*, 1998).

Other idiosyncratic reactions of veterinary importance include diazepam in cats (Center *et al.*, 1996) and sulfonamides in dogs (Trepanier *et al.*, 2003; Shenton *et al.*, 2004; Trepanier, 2004). The clinical presentation associated with diazepam in cats is similar to that described with carprofen in dogs. Idiosyncratic reactions to sulfonamides occur in about 0.25% of dogs and a variety of organ systems may be affected, hepatopathy being the third most reported sequela. Other effects may include polyarthropathy, which predominates in Doberman pinschers, thrombocytopenia, pyrexia and dermal drug eruptions.

## CONCLUDING REMARKS AND FUTURE DIRECTIONS

Research in the last decade has focused on understanding the different mechanisms for chemical-induced liver injury. Researchers have attempted to understand the molecular basis for injury and the contribution of individual cell types to ultimate hepatic pathology. Recently,

techniques such as microarray-based toxicogenomics, 2D gel electrophoresis, mass spectrometry-based proteomics and  $^1\text{H}$ -NMR spectroscopy-based metabolomics have attempted to further design novel hypotheses to test the molecular players involved in liver damage (Craig *et al.*, 2006; Blomme *et al.*, 2009; Kienhuis *et al.*, 2011).

Toxicogenomics will enable the detection of specific biomarkers used to predict adverse drug effects at low-level exposure (Kienhuis *et al.*, 2011). Several signature biomarkers have been elucidated that may eventually be useful in the diagnosis of hepatotoxicosis: serum proteomic analysis revealed increased concentrations of vitamin D-binding protein, malate dehydrogenase and purine nucleoside phosphorylase in several models of chemically induced hepatopathies. These enzymes were elevated in the serum before increases in conventional serum markers such as transaminase, alkaline phosphates or microscopic changes (Amacher *et al.*, 2005). Once validated for use in humans and domestic animals, these proteins are potentially predictive of hepatotoxicity. Use of these biomarkers will assist in identifying drugs that can cause serious adverse reactions, such as idiosyncratic liver injury, which cannot be easily discovered during conventional pre-clinical or clinical drug trials. Further, research involving transgenic and knockout models provides insight into the mechanistic and molecular basis of liver injury.

Genetic predispositions to idiosyncratic drug reactions have been elucidated in humans, such as sensitivity to diclofenac and other drugs and xenobiotics in patients with a mutation in the gene for multidrug resistance-associated protein 2. Mutations in the genes for superoxide dismutase and glutathione transferase also account for increased susceptibility to the toxic effects of certain drugs (Stirnemann *et al.*, 2010). Animal models for idiosyncratic drug reactions remain elusive, but form another area requiring investigation.

## Renal toxicity

Sharon M. Gwaltney-Brant

### INTRODUCTION

The kidney plays a vital role in maintaining homeostasis through the elimination of waste products, conservation of fluid and electrolyte balance, maintenance of acid–base balance, secretion of hormones and regulatory peptides, and metabolism and excretion of both endogenous compounds and xenobiotics. Although the kidney comprises roughly 0.5% of bodily mass, it receives up to 20–25% of cardiac output which can expose renal tissue to relatively high levels of blood-borne toxicants. The kidney may also be exposed to toxicants through the metabolic activation of xenobiotics by enzyme systems within the renal tubular epithelium, and through the process of urine concentration, the kidney can be exposed to higher concentrations of toxicants than other tissues. Injury to the kidney can lead to widespread systemic derangements, and due to limited regenerative ability, long-term renal insufficiency may result from exposure to nephrotoxic agents.

### FUNCTIONAL ANATOMY

Kidneys are paired organs residing ventrolaterally to the lumbar vertebrae in mammals. Mammalian kidneys are bean to horseshoe shaped with uniform exterior surfaces, although some species (e.g., bears, ox, whales) have multilobulated surfaces. Kidneys can be unipyramidal (e.g., horses, dogs, cats) or multipyramidal (e.g., pigs, ox) depending on the number of renal papillae into which renal lobes empty. Mammalian kidneys

are of equal size and are roughly the equivalent of three vertebrae in length. The surface of the kidney is covered by a fibrous capsule, and is brown-red in color in most species; in the cat, normal high fat content within the tubules results in a kidney that is a pale, yellow-gray color. Viewed on sagittal section, the kidneys have a medial indented hilar region from which renal artery, renal vein, lymphatics, nerves and ureter emerge. Viewing the cut surface of the sagittally incised kidney, the renal interior can be divided into two distinct sections, the cortex and medulla. The renal cortex in mammals comprises approximately 80% of the renal mass, and the normal cortex to medulla ratio is 1:2 to 1:3 in most species (Maxie and Newman, 2007). The medulla is divided into ray-shaped sections known as renal pyramids, which have their bases at the corticomedullary junction and apices that empty into the renal calyx (cats, ox) or pelvis (dogs, horses). From the hilar region, the ureter directs urine to the distal urinary bladder.

The functional unit of the kidney is the nephron, which is comprised of the renal corpuscle (Bowman's capsule and the glomerulus), proximal tubule, loop of Henle and distal tubule. The number of nephrons per kidney ranges from 200,000 in cats and 400,000 in dogs to 1,000,000 in humans. The ultimate number of nephrons is fixed at birth, although kidneys of altricial offspring of some species (e.g., dog, cat, pig) undergo nephrogenesis for several weeks after birth (Maxie and Newman, 2007). Renal blood flow originates from the renal arteries which are direct branches from the aorta. The kidneys receive 20–25% of cardiac output, allowing the entire plasma volume to be filtered approximately 100 times daily. Renal arteries progressively branch to form interlobar arteries, arcuate arteries, interlobular

arteries and afferent arterioles, which feed blood to the glomerulus. The high hydrostatic pressure from afferent arterioles provides the force for ultrafiltration of plasma by the glomerulus, a tuft of branching and anastomosing capillaries. The glomerular “sieve” consists of the capillary endothelium, basement membrane and epithelial *podocytes* that anchor foot processes (*pedicels*) within the lamina rara of the glomerular basement membrane (GBM). These pedicels are separated by filtration slits covered by slit diaphragms containing 6–9 nanometer diameter pores through which plasma is filtered, permitting filtration of compounds up to approximately 60 kilodaltons in size. The glomerular mesangium provides the supporting framework for the glomerular capillaries, and is composed of an extracellular matrix, contractile stellate cells which respond to vasoactive hormones and phagocytic cells which are involved in local immune reactions (Khan and Alden, 2002). The distal ends of glomerular capillaries merge to form efferent arterioles that progress further down the nephron and form the peritubular capillary network that surrounds the renal tubules and helps to drive the countercurrent absorption mechanisms responsible for concentration of the urine and regulation of electrolyte balance. The majority of renal blood flow and oxygen is expended in the cortex, making the medulla a relatively hypoxic area of the kidney.

Fluid filtered by the glomerulus enters Bowman’s capsule and flows into the proximal renal tubule. The proximal tubule is divided into three segments that differ anatomically and functionally. The most proximal segment,  $S_1$ , consists of the convoluted portion of the proximal tubule and possesses epithelial cells with tall brush borders, well-developed lysosome systems and numerous basally located mitochondria. The  $S_2$  segment extends from the end of the convoluted segment to the beginning of the straight segment and constitutes a transition segment.  $S_2$  segment epithelia have shorter brush borders, fewer mitochondria and fewer lysosomes than cells in the  $S_1$  segment. The  $S_3$  segment encompasses the remaining distal portion of the proximal tubule and extends into the outer reaches of the medulla. Oxygen consumption,  $\text{Na}^+/\text{K}^+$  ATPase activity and gluconeogenic capacity are greatest in the first two segments, while the  $S_3$  segment has higher transport capabilities for some compounds, such as ascorbic acid (Castro *et al.*, 2008). The  $S_3$  segment is also the site for metabolic activation of some toxicants.

In the proximal tubule, passive reabsorption of water and active reabsorption (via  $\text{Na}^+/\text{K}^+$  ATPases) of sodium occurs. Other solutes reabsorbed by the proximal tubule include potassium, calcium, phosphorus, bicarbonate, glucose, amino acids and proteins, and various xenobiotics, with each segment having a different range of and capacity for reabsorption. For instance, the  $S_1$  segment

is primarily responsible for the reabsorption of bicarbonate, glucose, amino acids and low molecular weight proteins. The proximal tubule ultimately reabsorbs 60–80% of solute and water filtered by the glomerulus. Excretory functions of the proximal tubule include the active secretion of weak organic anions and cations. The proximal tubular epithelium possesses cytochrome P450-dependent mixed function oxidases capable of metabolizing a variety of endogenous compounds and xenobiotics. Agents that are biotransformed to toxic metabolites (e.g., acetaminophen) can induce proximal renal tubular injury.

Filtrate passes from the proximal tubule into the loop of Henle, which has a thin-walled descending limb and a thick-walled ascending limb that extend to the level of the outer medullary region. In some nephrons, termed long-looped nephrons, the loop dips deeply into the inner medulla; in these nephrons, the proximal aspect of the ascending limb is thin-walled, becoming thick-walled as the tubule reaches the level of the outer medulla. Countercurrent exchange mechanisms within the loop result in the reabsorption of approximately 20% of filtered water and 25% of filtered sodium and potassium (Schnellmann, 2008). In the thin descending limb, water and interstitial solutes such as urea and electrolytes are able to freely pass into the tubule. At the level of the thin ascending limb, the tubule becomes impermeable to water and urea, and chloride and sodium ions are actively transported via  $\text{Na}^+/\text{K}^+$  ATPases. Because the loop of Henle resides largely within the poorly oxygenated renal medulla, the high oxygen demand of the  $\text{Na}^+/\text{K}^+$  ATPases make this segment especially susceptible to hypoxic injury (Brezis *et al.*, 1984).

The macula densa is composed of specialized cells located between the end of the thick ascending limb of the loop of Henle and the most proximal aspect of the distal tubule. This area is in close proximity to afferent arterioles, allowing for communication between the macula densa and afferent arteriole of the same nephron. An increase in intratubular solute concentration at the macula densa results in a feedback signal to the afferent arteriole, resulting in vasoconstriction and reduction of glomerular filtration rate (GFR). This feedback mechanism helps prevent massive loss of fluid and solute in the face of impaired renal tubular absorption. The proximal-most aspect of the renal distal tubule is responsible for reabsorption of most of the remaining intraluminal electrolytes such as sodium and potassium. The remaining segment of the distal tubule and collecting duct absorb remaining sodium, eliminate excessive potassium and hydrogen ions, and absorb additional water (influenced by antidiuretic hormone) as needed to regulate the volume and composition of the urine. Agents that disrupt the osmotic gradient of the medullary region (e.g., by increasing medullary blood flow) can disrupt

the ability of the kidney to concentrate urine. Collecting ducts progressively intersect and anastomose toward the renal papilla and ultimately empty into the renal calyx, renal pelvis, or ureter, depending on species. Peristaltic action of the ureter propels urine toward the urinary bladder for temporary storage and elimination.

In addition to its role in regulation of waste excretion and water/electrolyte balance, the kidney secretes a variety of hormones and regulatory peptides vital for normal systemic homeostasis. Secretion of erythropoietin by renal peritubular interstitial cells promotes red blood cell formation; significant chronic renal disease is often associated with anemia due to decreases in erythropoietin secretion. Renin secreted from the juxtaglomerular cells increases systemic and renal blood pressure and aldosterone release. Prostaglandins and prostacyclin are produced by a variety of renal cells and aid in regulation of renal vascular tone, mesangial contractility and processing of water and electrolytes by the renal tubules. The kidney also plays an important role in the xenobiotic clearance and/or metabolism.

## TOXIC EFFECTS ON THE KIDNEY

### Acute renal failure

Acute renal failure is defined as an abrupt decrease in renal function leading to retention of nitrogenous wastes (Langston, 2010), and is one of the most common manifestations of nephrotoxic injury (Schnellmann, 2008). The term *acute renal failure* is sometimes used interchangeably with *acute renal insufficiency* or *acute renal injury* (AKI). The latter term has been suggested as the proper term to use in order to encompass the entire spectrum of renal injury, from minor elevations of serum chemistry values (i.e., blood urea nitrogen and creatinine) to anuric renal failure.

The primary manifestation of AKI is a decrease in GFR leading to an excess of nitrogenous wastes in the blood (azotemia). Decreases in GFR may result from prerenal, renal or postrenal causes. Prerenal causes of decreased GFR include hypovolemia, renal vasoconstriction and poor cardiac output. Postrenal factors include obstruction of the ureters, bladder or urethra (e.g., bladder stones). Primary renal factors that can result in AKI leading to decreased GFR include tubular injury, glomerular injury, interstitial disease and renal vascular compromise. In humans, prerenal factors are said to account from 20 to 80% of cases of AKI, while renal factors account for 10 to 45% and postrenal factors account for 5 to 15% (Langston, 2010). Of causes of primary renal injury, ischemia/reperfusion and nephrotoxicosis are considered to account for over 90% of AKI cases (Schnellmann,

2008). Nephrotoxics damage the kidneys by a variety of different mechanisms including: (1) direct injury to renal tubular epithelium, leading to epithelial cell necrosis, sloughing and obstruction of tubules by cellular debris (tubular casts), (2) detachment of lethally injured cells from the basement membrane, resulting in back-leakage of filtrate across the exposed basement membrane and adherence of detached cells to sub-lethally injured cells still attached to the basement membrane causing lumen obstruction, (3) renal vasoconstriction, resulting in hypoxia and ischemic necrosis of renal structures, (4) damage to the glomerular filtration barrier, and (5) impairment of renal healing and repair (Counts *et al.*, 1995). Most nephrotoxics exert their damage at the level of the renal tubules, with many toxicants targeting specific segments of the tubules. For instance, aminoglycoside antibiotics cause damage primarily to the S<sub>1</sub> and S<sub>2</sub> segments of the proximal tubule, while mercuric chloride-induced injury is restricted to the S<sub>3</sub> segment at low doses, extending into the S<sub>2</sub> and S<sub>1</sub> segments only at higher doses (Diamond and Zalups, 1998).

The clinical signs of acute renal injury and/or failure can include polydipsia, nausea or vomiting, lethargy, anorexia, weakness, dehydration and polyuria/oliguria/anuria. More severe cases may have halitosis, oral ulceration, abdominal (renal) pain, palpably enlarged kidneys and cardiac arrhythmias. Clinical laboratory abnormalities indicative of AKI include elevations in blood urea nitrogen and serum creatinine (azotemia), hyperphosphatemia, hyper- or hypokalemia and metabolic acidosis. *Uremia* is the term used when azotemia is accompanied by typical clinical signs of AKI. Advanced cases of uremia may present with gastrointestinal ulceration, anemia, peripheral neuropathy, encephalopathy and cardiac dysfunction.

The ability of the kidney to heal following an acute toxic insult is dependent upon several factors including the dose and type of toxicant, the amount of functional kidney remaining, the presence and severity of secondary uremic conditions (e.g., soft tissue mineralization) and the degree of medical intervention and supportive care provided during the acute crisis. Mild to moderate renal tubular injury with retention of tubular basement membranes have a reasonable prognosis for tubular regeneration provided that supportive care is administered until tubules have had a chance to recover. In uncomplicated acute tubular injuries, regeneration of epithelial cells generally begins after about 7–10 days following the renal insult; in mild cases, full recovery of architecture may occur within 2–3 weeks, with longer recovery periods being required for more severe renal injury (Maxie and Newman, 2007). In situations where nephrons have been fully obstructed by cellular debris or crystals, or if basement membrane integrity is lost, regeneration may be incomplete, resulting in

long-term renal insufficiency and/or progression to chronic renal failure.

## Chronic renal failure

Chronic renal failure (CRF) is most commonly the result of long-term exposure to toxicants, and many of the alterations seen in CRF are related to the secondary compensatory changes triggered by the initial injury. Upon loss of nephrons (and thus decrease in overall renal GFR), hemodynamic alterations occur that increase the blood flow and pressure to surviving nephrons in an attempt to reestablish normal whole-kidney GFR. Although changes such as increased glomerular pressures can help to maintain overall GFR, these increased pressures may contribute to glomerular sclerosis, tubular atrophy and interstitial fibrosis, thus furthering the progression of renal injury (Brenner *et al.*, 1982). Increased pressure within glomerular capillaries results in an increase in volume of the glomerular tuft, glomerular hypertrophy and intraglomerular hypertension. Consequences of these changes include hyaline accumulation within glomerular capillary walls, mesangial dysfunction associated with matrix accumulation and microaneurysm formation, and thrombosis due to endothelial injury (Polzin, 2010). As the glomerulus expands, podocytes are unable to maintain the integrity of slit diaphragms and focal denudation of GBM occurs, allowing leakage of larger proteins into the glomerular filtrate (proteinuria). In addition to hemodynamically induced progression of CRF, there is

evidence to suggest that T-lymphocytes and interleukin-6 contribute to the ongoing interstitial fibrosis in dogs with chronic progressive kidney disease (Yhee *et al.*, 2008).

Clinical effects associated with CRF include uremia, gastrointestinal disorders (uremic gastritis, uremic enterocolitis), polyuria, polydipsia, nocturia, dehydration, atrial hypertension, peripheral neuropathy, uremic encephalopathy, myopathy, anemia, platelet dysfunction, renal secondary hyperparathyroidism, cachexia and hypokalemia (especially in cats) (Polzin, 2010). Immunosuppression is a potential complication of CRF in humans, and studies of dogs with CRF have shown impaired immunological function as well (Kravola *et al.*, 2010). Animals with CRF may show few outward signs of illness until late in the course of their disease; in some instances acute decompensation may occur during periods of physical or emotional stress (Hosseini and Hosseini, 2008). Lesions found in animals with CRF include kidneys that are small and irregular in shape, with uneven capsular surfaces. On cut section, pale streaks (fibrosis) may be seen within the interstitium and the parenchyma may be gritty upon cutting due to mineralization and/or crystal deposition.

## Patterns of toxic renal injury

Identification of the target site of action of nephrotoxins can assist in determining the functional impact and potential mechanism of toxicity (Figure 18.1). Toxicants that are directly toxic to cells may cause injury to the glomerulus or the S<sub>1</sub> segment of the proximal tubule as

**FIGURE 18.1** Sites of renal damage, including factors that contribute to the kidney's susceptibility to damage. ACE: angiotensin converting enzyme; NSAIDs: nonsteroidal anti-inflammatory drugs; HgCl<sub>2</sub>: mercuric chloride. (Adapted from Berl T and Bonaventura JV (1998) *Atlas of Diseases of Kidney*, Schrier RW (ed.). Blackwell Publishing, Philadelphia, with permission.)

they first enter the nephron. Conversely, direct-acting toxicants may be dilute in the initial ultrafiltrate, and may not cause injury until they reach the more distant nephron, where they may reach toxic concentrations as water is gradually reabsorbed and/or the pH changes.

Some toxicants require bioactivation in order to exert their toxic effects, so they may cause site-specific injury to the S<sub>3</sub> segment of the proximal tubule, where bioactivation processes are most active. A list of nephrotoxicants and their primary sites of action can be seen in Table 18.1.

TABLE 18.1 Urinary tract toxicants listed by site of injury

Toxicant	Species	Lesion	Comment
<b>Glomerular injury</b>			
Bacterial endotoxin (hemolytic-uremia syndrome)	All	Mesangiolysis	Intravascular fibrin deposition of glomerular capillaries (Schwartzman reaction)
Crotalid snake venom	All	Mesangiolysis	Also tubular degeneration
Cyclosporine	Dogs, cats	Thrombotic microangiopathy	
Gold salts	Dogs	Membranous glomerulonephritis	Also acute tubular necrosis, vasculopathy, interstitial fibrosis
Mercury	Ox	Membranous glomerulonephritis; proximal tubule degeneration and necrosis	Affects S <sub>1</sub> segment of proximal tubule
<b>Proximal tubular injury</b>			
Acer rubrum (red maple)	Horses	Acute tubular degeneration and necrosis; hemoglobin casts in tubules	
Acetaminophen	All	Acute tubular degeneration and necrosis	Metabolic activation results in damage to S <sub>3</sub> ; hepatotoxicity more common
<i>Amaranthus</i> spp.	Herbivores, especially pigs, calves	Acute tubular degeneration and necrosis; perirenal edema	See text for more information
Aminoglycoside antibiotics	All	Acute tubular degeneration and necrosis	Predominantly S <sub>1</sub> and S <sub>2</sub> segments; see text for more information
Amphotericin B	Dogs, cats	Acute tubular degeneration and necrosis; tubular dilatation; glomerular and interstitial mineralization	Arteriolar vasoconstriction results in decrease in GFR
Arsenic	All	Acute tubular degeneration and necrosis, cortical necrosis (dogs)	All segments
Cadmium	All	Acute tubular degeneration and necrosis	Glomerular injury reported in seals <sup>a</sup>
Cantharadin (blister beetle, <i>Epicutata</i> spp.)	Herbivores, especially horses	Acute tubular degeneration and necrosis; renal cortical hemorrhages; hyperemia and hemorrhage of mucosa of renal crest, ureter, bladder, urethra	Vesicant effect on mucosa of alimentary tract, cardiac lesions
Carbon tetrachloride	All	Tubular degeneration and necrosis	Hepatic injury most prominent
Cephalosporin antibiotics (and other $\beta$ -lactam antibiotics)	All	Tubular degeneration and necrosis	High intracellular concentrations in S <sub>3</sub> segment due to action of organic ion transporter result in cell injury
Cholecalciferol (1,25-dihydroxy cholecalciferol, vitamin D <sub>3</sub> ), calcitriol, calcipotriene, <i>Cestrum diurnum</i> , <i>Solanum</i> spp., <i>Trisetum</i> spp.	All	Tubular degeneration and necrosis; mineralization	Renal ischemia due to vasoconstriction and mitochondrial calcification secondary to hypercalcemia <sup>b</sup>
Cisplatin	Dog	Tubular degeneration and necrosis	Primary effect on S <sub>3</sub> segment due to metabolic activation
Citrinin	All species, pigs most common	Tubular degeneration and necrosis	Primary effect on S <sub>2</sub> segment, thick ascending limb, distal convoluted tubule and collecting ducts; see text for more information
Copper	Sheep, other ruminants less common	Tubular degeneration and necrosis; hemoglobinuric and bile nephrosis (gunmetal kidney)	Non-ruminants develop liver injury without hemolysis
Ethylene glycol	All, dogs and cats most common	Tubular degeneration and necrosis; intratubular calcium oxalate crystals	Oxalate crystals may be found in vessels of meninges, heart, liver, intestinal mucosa; see text for more information

(Continued)

TABLE 18.1 (Continued)

Toxicant	Species	Lesion	Comment
<i>Lantana</i> spp.	All grazing animals except horses	Tubular degeneration and necrosis	Lesions primarily in liver; secondary photosensitization; cardiac lesions
Lead	All	Tubular degeneration and necrosis; intranuclear inclusion bodies; karyomegaly of tubular epithelium	
<i>Lilium</i> spp.	Cats only	Tubular degeneration and necrosis; vascular fibrinoid necrosis	See text for more information
NSAIDs (see distal tubule section for phenylbutazone and flunixinmeglumine)	Dogs, cats, vultures, other species likely susceptible	Tubular degeneration and necrosis; occasionally papillary necrosis in dogs	See text for more information
Ochratoxin A	All, pigs most commonly affected	Tubular degeneration and necrosis; cystic tubular dilatation; interstitial fibrosis; renal edema in chickens	Primary effect on S <sub>3</sub> segment due to bioactivation; <sup>c</sup> carcinogen; see text for more information
Oosporein	Chickens	Tubular degeneration and necrosis; interstitial pyogranulomatous inflammation and fibrosis	Periodic-acid-Schiff-positive granules in macula densa <sup>d</sup>
Oxalic acid, soluble oxalates ( <i>Halogetonglomeratus</i> , <i>Sarcobatusverniculatus</i> , <i>Rheum rhaponticum</i> , <i>Rumex</i> spp., <i>Chenopodium</i> spp.)	All, ruminants and pigs most common	Tubular degeneration and necrosis; intratubular calcium oxalate crystals	Precipitation of soluble oxalates with serum calcium; hypocalcemic tetany possible
Paraquat	All	Tubular degeneration and necrosis	Pulmonary lesions most common effect (progressive pulmonary fibrosis); corrosive lesions in GI tract
Pine oil	Cats	Tubular degeneration and necrosis	Hepatic lesions more prominent
Pyrrolizidine alkaloids ( <i>Amsinckia</i> , <i>Crotolaria</i> , <i>Cynoglossum</i> , <i>Echium</i> , <i>Heliotropium</i> , <i>Senecio</i> spp.)	All, predominantly horses, cattle, pigs	Tubular degeneration and necrosis; megalocytosis of tubular and glomerular cells	Hepatic lesions more prominent; secondary photosensitization, hepatic encephalopathy
Quercus spp. (Oaks)	Grazing animals, cattle most common	Tubular degeneration and necrosis; perirenal edema	See text for more information
Sulfonamide antibiotics	Ruminants	Tubular degeneration; grossly visible intratubular crystals	
<i>Vitis</i> spp. (grapes, raisins, Zante currants)	Dogs	Tubular degeneration and necrosis	See text for more information
Zinc	All	Tubular degeneration and necrosis; hemoglobinuricnephrosis	
<b>Distal tubular/collecting duct injury</b>			
Fluoride	All	Distal tubular degeneration and necrosis	
Melamine: cyanuric acid	Dogs, cats, raccoon dogs, pigs, rats, fish; others likely susceptible	Distal tubular degeneration and necrosis; crystals in distal tubules and collecting ducts	See text for more information
<b>Interstitial injury</b>			
<i>Vicia</i> spp. (vetch)	Grazing animals, primarily cattle	Eosinophilic granulomatous nephritis	Lesions can occur in any organ
<b>Lower urinary tract injury</b>			
Cyclophosphamide	Dogs	Hemorrhage and necrosis of urinary bladder	Bioactivation and concentration of toxic metabolites in urine
Ptaquiloside ( <i>Pteridium</i> spp., bracken fern)	Cattle	Necrosis and hemorrhage of urinary bladder; urinary bladder neoplasia	Enzootic hematuria
Ptaquiloside ( <i>Sorghum</i> spp.)	Horses	Necrosis and hemorrhage of urinary bladder	Equine cystitis ataxia syndrome

## Glomerular injury

The glomerular capillaries are the first component of the nephron to be exposed to blood-borne toxicants. The glomerular cells, matrix and mesangium are susceptible to toxic injury by several different mechanisms including direct injury to cellular components, formation of oxygen-derived free radicals, disruption of extracellular substrates (e.g., basement membranes), immune-mediated injury and disruption of renal hemodynamics (Khan and Alden, 2002). Direct injury or injury secondary to reactive oxygen intermediates can result in endothelial loss, glomerular podocyte injury and necrosis of mesangial cells and substrate (mesangiolysis). Further damage may occur secondary to cytokines released by inflammatory cells responding to the site of injury. Alterations in the GBM secondary to cellular injury can result in disruption of the glomerular filtration barrier, leading to proteinuria. Deposition of and immune-mediated reaction to various toxicants (e.g., mercurial, gold salts) can result in thickening of the GBM, disrupting the glomerular filtration barrier and leading to membranous glomerulonephropathy.

## Proximal tubular injury

Tubular injury is the most common pattern of renal injury induced by toxicants and the proximal tubule is most frequently affected by nephrotoxicants (Schnellmann, 2008). Damage to the proximal tubule may occur due to direct damage from toxicants, metabolic activation of toxicants, ischemia-reperfusion or physical or chemical disruption of endothelium and/or basement membrane. The S<sub>1</sub> segment is the most vulnerable to injury from toxicants that exert direct injury as the epithelium in this area is exposed to the toxicant first. The proximal convoluted tubule epithelium is actively involved in endocytosis of various compounds that bind to the brush border, sequestering the compounds in phagolysosomes. When this process is overwhelmed by the presence of certain toxicants (e.g., aminoglycoside antibiotics), loss of phagolysosome membrane integrity occurs, resulting in lysosomal leakage and cell injury or necrosis (Khan and Alden, 2002). This type of injury is most commonly associated with the S<sub>1</sub> and S<sub>2</sub> segments of the proximal tubule. In contrast, the straight segment (S<sub>3</sub>) is most susceptible to injury by metabolic activation, transporter-associated accumulation and ischemia reperfusion.

## Distal nephron/renal papillary injury

Toxic injury to the distal nephron is relatively uncommon, and injury to this area generally manifests as

decreased urine concentration ability or defects in acid secretion. Injury to the renal papilla is most commonly seen with chronic consumption of non-steroidal anti-inflammatory drugs (NSAIDs), although use of NSAIDs in hypovolemic animals or in conjunction with other nephrotoxicants (e.g., aminoglycoside antibiotics) has also been associated with the development of renal papillary necrosis (Talcott, 2006).

## NEPHROTOXIC AGENTS

### Mycotoxins

#### Ochratoxins

Ochratoxins are produced by various species of the fungi *Aspergillus* and *Penicillium* and are produced on a variety of cereal grains, cottonseed, nuts, dried beans and coffee beans (Haschek *et al.*, 2002). OchratoxinA (OTA) is the most common and most toxic of the ochratoxins that have been identified to date. The co-production of penicillic acid by *Penicillium ochraeus* or citrinin by *Aspergillus* spp. or *Penicillium* spp. greatly enhances the toxicity of OTA (Haschek *et al.*, 2002; Kumar *et al.*, 2007). OTA is thought to be the causative factor in endemic Balkan nephropathy of humans (Maxie and Newman, 2008). Ochratoxin toxicosis has been reported in a variety of animal species including swine, ducklings, horses, chickens, rabbits, turkeys, dogs and fish (Kitchen *et al.*, 1977; Haschek *et al.*, 2002; Kumar *et al.*, 2007; El-Sayed *et al.*, 2009). Cattle are thought to be resistant due to degradation of ochratoxins within the rumen, although pre-ruminant calves are susceptible (Haschek *et al.*, 2002). In domestic animals, ochratoxicosis is most commonly reported in pigs and chickens as a subchronic to chronic disease affecting growth and production (Maxie and Newman, 2008; Sakthivelan and Sudhakar Rao, 2010). Pigs are considered to be the most sensitive species, with chronic toxicosis occurring following ingestion of diets containing 0.2–4ppm OTA, while broiler chickens develop toxicosis at 2ppm OTA (Haschek *et al.*, 2002). The renal lesions in pigs consist of proximal tubular degeneration and atrophy with interstitial fibrosis and infiltration by mononuclear cells. Cystic dilatation of degenerated tubules occurs, which can lend a pitted, irregular appearance to the renal capsule, and glomerular hyalinization has been reported in severe cases. In acute cases, perirenal edema may occur (Maxie and Newman, 2008). Additional lesions of OTA toxicosis in pigs include multifocal necrotizing enteritis, fatty degeneration of the liver and lymphoid necrosis (Szczzech *et al.*, 1973). In broilers, OTA causes renal edema and renal tubular necrosis (Huff *et al.*, 1975). OTA is teratogenic,

mutagenic and carcinogenic, inducing renal tumors in rats (Haschek *et al.*, 2002).

### Citrinin

Citrinin is produced by toxic strains of several *Penicillium*, *Aspergillus* and *Monascus* spp. (Bennett and Klich, 2003), and has been associated with rice, wheat, oats, rye, corn, barley, vegetarian foods colored with red *Monascus* pigments and naturally fermented sausages from Italy. Citrinin is often found in association with OTA and is less toxic than OTA (Kitabatake *et al.*, 1993). Dogs receiving citrinin at dosages of 80 micromoles/kg intravenously or 10mg/kg orally developed proteinuria and glucosuria and ultrastructural changes in the epithelium of the S<sub>2</sub> segment, thick ascending limb, distal convoluted tubule and collecting ducts (Kitchen *et al.*, 1977; Krejci *et al.*, 1996). Dogs given oral 10mg/kg citrinin twice at 24 hour intervals developed similar lesions and developed glucosuria, proteinuria and granular casts in the urine; glucosuria was the earliest abnormality noted and persisted for 5 days, as did proteinuria (Kogika *et al.*, 1993). Cylindruria persisted from days 1 to 15, and renal values (BUN, creatinine) were elevated from days 2 to 5. Clinical signs in dogs administered 10mg/kg citrinin per day for 14 days included anorexia, retching, tenesmus, weight loss, prostration and death. Citrinin is teratogenic, embryotoxic and a putative carcinogen.

## Drugs

### Aminoglycoside antibiotics

Aminoglycoside antibiotics exert their nephrotoxic effects through induction of apoptosis and necrosis within the renal tubular epithelial cells of the proximal convoluted tubule as well as the distal tubules and collecting ducts (Lopez-Novoa *et al.*, 2011). Within these cells, aminoglycosides internalized through endocytosis accumulate in lysosomes, Golgi apparatus and endoplasmic reticulum. As the aminoglycoside concentration increases beyond a threshold level, the endosomal membranes become disrupted and the drug leaks into the cytosol where it activates the intrinsic apoptotic pathway, increases production of reactive oxygen intermediates, and interacts with mitochondria to interrupt the respiratory chain. Interaction with endoplasmic reticulum and Golgi apparatus result in dysfunction in protein synthesis and packaging. In sub-lethally affected cells, aminoglycosides interfere with cell membrane transporter systems, altering tubular reabsorption and threatening epithelial cell viability. Cellular necrosis and apoptosis result in the accumulation of cellular residues in the tubular lumen, causing obstruction which increases the intratubular hydrostatic pressure. This

back-pressure results in leakage of ultrafiltrate into the interstitium and peritubular capillaries and reduces the glomerular filtration pressure gradient, resulting in decrease in GFR. Aminoglycosides also have some direct glomerular effects including mesangial contraction, mesangial cell proliferation and alteration of filtration barrier selectivity. Toxicosis from aminoglycosides results in loss of urine concentration ability, polyuria, proteinuria, hematuria, cylindruria, azotemia and acute renal failure. In spite of the significant renal injury that may develop due to aminoglycoside exposure, the renal effects are generally considered reversible once the drug is withdrawn (Maxie and Newman, 2008). Additional adverse effects of aminoglycoside antibiotics include ototoxicity and induction of neuromuscular blockade.

### NSAIDs

Non-steroidal anti-inflammatory drugs are the most widely used analgesics in veterinary medicine and are the most common drugs involved in accidental overdoses in companion animals (Sebastian *et al.*, 2007; Gwaltney-Brant, 2007). In both therapeutic and overdose situations, the potential of most NSAIDs to have deleterious effects on the kidney must be considered. The adverse effects of NSAIDs on the kidney result from the inhibition of cyclooxygenases (COX) which results in decreased synthesis of prostaglandins (PGs). COX has two distinct isoforms, COX-1 and COX-2. COX-1 is constitutively expressed in most tissues through the body while COX-2 is normally expressed in tissues at low levels, but can be induced in the presence of pro-inflammatory mediators that are expressed in sites of inflammation, pain or injury (Radi, 2009). COX-1 is the most abundant isoform expressed in the kidneys, and is located in the renal vasculature, collecting ducts and papillary interstitial cells. COX-2 is minimally expressed in the kidney and its localization within the different areas and impact on production of PGs in the kidney is species and maturation dependent. The kidney is a major site of PG synthesis, and PGs exert a variety of diverse functions within the kidney, including modulation of renal blood flow and GFR, regulation of sodium excretion and influencing renin release. PGs produced through the action of COX-1 are considered "protective," as inhibition of these PGs is associated with the majority of adverse effects from NSAIDs. NSAIDs such as ibuprofen are non-selective inhibitors of both COX isoforms, while newer NSAIDs may target COX-2, sparing COX-1 and resulting in fewer gastrointestinal and renal adverse effects (Khan and Alden, 2002). However, COX selectivity can be lost in overdose situations. The primary impact of COX-induced inhibition of PG synthesis in the kidney is reduction of renal blood flow, resulting in ischemia. The medulla and renal papillae

are at increased risk for NSAID-induced hypoxic injury due to their low oxygenation and relatively slow blood flow that predisposes to accumulation of toxic substances (Radi, 2009). Dogs, rats, mice and pigs are thought to be most sensitive to NSAID-induced papillary necrosis (Khan and Alden, 2002). Clinical effects of NSAID-induced renal injury include polyuria, polydipsia, dehydration, electrolyte imbalances and azotemia. Acute renal failure, interstitial nephritis and nephrotic syndrome have also been reported. Non-renal effects of NSAIDs include gastrointestinal ulceration.

## Metals

### Cadmium

The primary sources of exposure to cadmium are due to contamination of food, water and air. Cadmium in soil can be taken up by plants, and cadmium in water can bioaccumulate in shellfish. Inhalation exposure to cadmium can occur through exposure to industrial exhaust, fossil fuel combustion products and cigarette smoke; the latter is one of the major non-occupational sources of inhaled cadmium in humans (Gwaltney-Brant, 2002). Acute cadmium toxicosis primarily manifests as pulmonary injury, while nephrotoxicity resulting from cadmium is most commonly due to chronic exposure. Cadmium is poorly absorbed via the gastrointestinal tract, with less than 5% of ingested cadmium being absorbed; however, inhaled cadmium is more readily absorbed into the blood, where it binds to metallothionein, a 6800 dalton, cysteine-rich protein. Metallothionein transports cadmium primarily to the kidney and liver, with lesser amounts accumulating in bone and testicle. The cadmium-metallothionein complex is filtered through the glomerulus and reabsorbed from the filtrate into the proximal renal tubules by endocytosis (Khan and Alden, 2002). Within the phagolysosome, metallothionein is hydrolyzed, which releases the cadmium; the free cadmium triggers the *de novo* synthesis of additional metallothionein. Once the level of intracellular cadmium exceeds a species-specific threshold of tolerance (10–200 mcg/g wet weight), cellular injury progresses. Cadmium-injured cells have decreased reabsorptive capacity and decreased ability to concentrate urine (Gwaltney-Brant, 2002). Low molecular weight proteinuria (particularly  $\beta_2$ -microglobulinuria), amino aciduria, calciuria and glucosuria develop. Renal lesions include proximal tubular cell degeneration and necrosis, granular casts, hyaline casts, tubular atrophy, interstitial inflammation and interstitial fibrosis. Additional chronic renal lesions include fatty degeneration of pars recta tubular epithelium, nephrocalcinosis and glomerular disease resembling immune

complex glomerulonephritis. Extra-renal effects of cadmium include osteoporosis and osteopenia, hepatocellular necrosis, myocardial injury and testicular injury. Cadmium is a mutagen and putative carcinogen.

### Lead

The incidence of lead toxicosis has declined in the United States since the banning of lead-based paints in residential domiciles in 1977 and leaded gasoline in 1996 (with significant reductions in use of leaded gasoline for the prior 20 years). However, lead is still present in the paint of many older homes as well as common household items such as toys, artists' paints, linoleum, lead weights, lead fishing sinkers and ornaments. Additionally, despite bans on the use of lead shot for hunting waterfowl lead ammunition is still widely used on upland game, and lead toxicosis is still a significant cause of death among scavengers such as eagles and condors (Hunt *et al.*, 2009; Stauber *et al.*, 2010). Birds with lead toxicosis frequently present with emaciation and evidence of renal tubular degeneration (Pattee *et al.*, 2006). Acute lead toxicosis is most commonly associated with neurological signs in mammals, while chronic lead toxicosis can result in dysfunction of a variety of organ systems including gastrointestinal, neuromuscular, central nervous, hematological and renal (Gwaltney-Brant, 2002). Degeneration and necrosis of proximal renal tubules results in oliguria, amino aciduria, glucosuria and altered tubular ion transport. Acute renal failure may occur following exposure to lead, but chronic renal failure is more common. Dense, homogeneous, eosinophilic intranuclear inclusion bodies may be visualized in affected renal tubular cells; although suggestive for lead toxicosis, these inclusions are not pathognomonic as they can occur following exposure to other metals such as bismuth.

## Plants

### *Amaranthus* spp.

The pigweed family includes several different species capable of producing toxicosis, but *Amaranthus retroflexus* is the species most commonly associated with disease in domestic animals (Burrows and Tyrl, 2001). Renal injury from pigweed has been reported in pigs, cattle and sheep. Other herbivorous species are likely susceptible, although the disease was not able to be reproduced in rabbits fed *A. retroflexus* (Schamber and Misek, 1985). The toxic principle is not known. Although pigweeds do contain some oxalates, the levels are low and the clinical syndrome and lesions caused by pigweed toxicosis are not consistent with those seen in oxalate nephrosis (Burrows and Tyrl, 2001). Clinical signs generally begin

following several days of ingesting the plant, although renal lesions have been identified within 24 hours of ingestion. Clinical signs include weakness, ataxia, knuckling of pasterns, recumbency, paralysis and coma; death occurs within 1–2 days of onset of signs. Gross lesions of pigweed toxicosis include widespread edema, most prominently around the kidneys, rectum and omentum. Kidneys are pale and normal to swollen in size. Histopathologic changes within the kidney include interstitial edema, scattered hemorrhages and proximal tubular degeneration and necrosis. Dilated tubules and tubules filled with necrotic debris are often present and interstitial fibrosis may be present in chronic cases. Extra-renal lesions include edema and ulceration of the digestive tract.

#### *Lilium spp. and Hemerocallis spp.*

Ingestion of some species of the genera *Lilium* and *Hemerocallis* (Table 18.1) by cats has resulted in a potentially fatal renal dysfunction that has not been successfully reproduced in other species including dogs, rats and rabbits (Rumbeiha *et al.*, 2004). Although the toxic principle remains unknown, Rumbeiha *et al.* were able to demonstrate that the toxic effects originated from an aqueous floral extract of the Easter lily. All parts of the plant, including pollen, are toxic, and even small ingestions can result in significant renal injury (Fitzgerald, 2010). Prevention of serious renal injury can often be achieved if aggressive intravenous fluid therapy is instituted within the first 18 hours following exposure. Clinical effects include vomiting, depression, polyuria, polydipsia, azotemia, glucosuria, proteinuria and isosthenuria. Serum creatinine levels tend to elevate disproportionately to blood urea nitrogen. Histopathologic lesions include proximal convoluted tubule degeneration and necrosis with denudation of basement membrane and filling of tubular lumens with cellular debris (Rumbeiha *et al.*, 2004). Extra-renal lesions include vacuolar degeneration of pancreatic acinar cells.

#### *Quercus spp.*

Oak foliage and acorns provide forage to a variety of wildlife and livestock, but when oak is the primary source of feed for more than a few days, toxicosis can develop (Burrows and Tyrl, 2001). Oak buds, acorns and young leaves are involved in the majority of reported livestock poisonings and most oak species have, at one time or another, been implicated in animal poisonings. Cattle are most commonly affected, and reports in other species such as horses, goats and sheep are rare. The primary toxic principles in oak are tannins, phenolic and polyphenolic compounds such as ellagic and gallic acids, and tannin metabolites such as pyrogallol. At toxic doses, oak tannins precipitate proteins in the digestive

tract, causing erosions and ulcerations as well as altering mucosal absorption barriers. Increased absorption of polyphenolic tannins via injured mucosa results in damage to the liver and kidney; in rats, gallic acid was identified as the compound responsible for renal tubular necrosis (Harris *et al.*, 1966). Clinical signs begin 2 days to a week or longer after animals have been consuming large amounts of oak. Affected cattle initially develop anorexia, depression, rumen stasis and constipation which are followed by diarrhea (+/– blood), dehydration, colic, polyuria and subcutaneous edema of ventral areas such as neck, brisket, abdomen and perineum (Panciera, 1978). Clinical pathologic evaluation of serum reveals metabolic acidosis, elevations in BUN and serum creatinine, and electrolyte abnormalities (e.g., hyperkalemia). Cattle with severe renal injury become weak and die, while less severely affected animals may survive, although many will become chronically debilitated due to persistent renal insufficiency (Burrows and Tyrl, 2001). The disease progression is similar in other species, though sheep and goats do not develop appreciable edema and horses tend to have more severe diarrhea (+/– blood), colic and tenesmus. Gross findings include fluid accumulations within body cavities, subcutaneous edema, mesenteric edema and retroperitoneal edema (especially perirenal). Kidneys are swollen, pale and may have petechiae within the cortex; chronic cases may have shrunken, irregular and fibrotic kidneys. Extra-renal lesions include edema, congestion, erosions and ulcerations of the alimentary tract mucosa and some cases may have hepatocellular degeneration.

#### *Vitis spp.*

Ingestion of members of *Vitis* spp., including grapes, raisins and Zante currants, has been associated with acute renal failure in dogs (Morrow *et al.*, 2005) and, anecdotally, cats and ferrets (ASPCA Animal Poison Control Center, unpublished data). The toxic principle is unknown, but attempts to identify known nephrotoxins such as mycotoxins, pesticides, vitamin D<sub>3</sub> and heavy metals have been unsuccessful. Affected dogs generally demonstrate vomiting and/or diarrhea within 12 hours of ingestion of grapes or raisins, accompanied by anorexia, lethargy and abdominal discomfort in some cases (Morrow *et al.*, 2005). Severely affected dogs rapidly progress to anuria, and death or euthanasia occurs within 23–289 hours. Histopathological changes in the kidney include renal tubular degeneration and necrosis, primarily in the proximal tubules. Extensive sloughing of proximal tubule epithelium results in extensive necrotic debris within tubular lumens. Extra-renal lesions consist of centrilobular hepatic degeneration or necrosis, myocardial necrosis, soft tissue mineralization and fibrinous arteritis in colon, myocardium and aorta.

## Miscellaneous

### Ethylene glycol

The most common cause of ethylene glycol toxicosis in domestic animals is via the consumption of automotive antifreeze, and dogs and cats are the most commonly affected species, although all mammals are susceptible to toxicosis. Ethylene glycol intoxication has three distinct stages: (1) initial CNS depression and derangement due to an alcohol-like effect on the brain, (2) profound metabolic acidosis with significant cardiorespiratory effects due to formation of acidic metabolites of ethylene glycol and (3) acute renal failure due to renal tubular injury (Thrall *et al.*, 2006). Renal tubular injury is due to direct action of the nephrotoxic metabolites glycoaldehyde and glyoxylate on the renal tubules as well as mechanical injury and obstruction by calcium oxalate crystals (Thrall *et al.*, 2006; Maxie and Newman, 2007). Calcium oxalate crystalluria is considered by some to be a hallmark of ethylene glycol, but crystalluria is present in less than half of all intoxications. Therefore, the absence of oxalate crystals does not eliminate ethylene glycol as a potential toxicant. Renal changes associated with ethylene glycol intoxication include pale, swollen kidneys, which may be gritty when cut. Microscopically, proximal tubular degeneration and necrosis is associated with the deposition of birefringent, light yellow crystals arranged in sheaves, rosettes or prisms (Maxie and Newman, 2007). Oxalate crystals may also be found within tubular lumens, within renal tubular epithelial cells and within the interstitium (Figure 18.2). Animals surviving more than a few days may show areas of tubular regeneration and/or interstitial fibrosis. Extra-renal lesions may

include deposition of oxalate crystals within small vessels of the brain, heart, liver and intestinal mucosa.

### Melamine:cyanuric acid

In North America in 2007, the discovery of renal injury in dogs and cats ingesting commercial pet foods led to the recall of over 60 million cans and pouches of “cuts and gravy”-style pet food contaminated with melamine and cyanuric acid. The contamination was found to have originated in wheat gluten from China, where the melamine had been added to artificially inflate the apparent protein level of the product. Cyanuric acid is a hydrolysis product of melamine that may also have either been intentionally added or coincidentally present as a melamine by-product (Puschner *et al.*, 2007). Subsequent to the pet food recall of 2007, the contamination of various food sources by melamine has been identified in several countries around the world including Italy, China, Spain, Korea, Taiwan and other Asian countries (Brown *et al.*, 2007; Gonzalez *et al.*, 2009; Yhee *et al.*, 2009; Brown and Brown, 2010; Cocch *et al.*, 2010). By themselves, melamine and cyanuric acid are of low toxicity, but in combination these compounds precipitate in acidic environments to form melamine cyanurate crystals (MCA) (Puschner *et al.*, 2007). In animals ingesting feed containing melamine and cyanuric acid, precipitation of MCA in the renal tubules has been associated with tubular injury, interstitial edema and renal failure. The exact mechanism of renal injury is not known, although mechanical injury from deposition of the large crystals is likely contributory. In cats, acute renal failure was induced within 48 hours following oral administration of 32 mg/kg

**FIGURE 18.2** Ethylene glycol poisoning, canine kidney. A. Tubules are lined by degenerate and attenuated epithelium and contain crystalline material consistent with calcium oxalate crystals. H&E stain, 100 ×. (Photo courtesy Thomas Brant, Mahomet, IL.) B. Tubules contain birefringent crystalline material consistent with calcium oxalate crystals. **FIGURE 18.3** Melamine:cyanurate crystals, feline kidney. The corticomedullary junction is obscured by a broad, dark red band of hemorrhage. Fine dots of 0.1 cm long threads of an opaque, variably white to yellow substance (i.e., crystals) are observed. These crystals extend from the papilla of the medulla into the obscured corticomedullary junction and are in parallel with the medullary rays. They are most concentrated at the renal crest. (Courtesy of Drs. Patricia Pesavento and Birgit Puschner, University of California, Davis.).

of melamine and cyanuric acid. MCA-induced nephropathy has been documented in humans, pigs, dogs, cats, fish, raccoon dogs and rats (Reimschuessel *et al.*, 2008; Bhalla *et al.*, 2009; Gonzalez *et al.*, 2009; Yhee *et al.*, 2009; Brown and Brown, 2010), although most species are likely susceptible. Affected animals develop clinical signs typical of renal injury: vomiting, anorexia, lethargy, polyuria/oliguria and dehydration. Renal lesions include hemorrhage and edema of the interstitium, predominantly in the medullary region (Figure 18.3). Degeneration and necrosis of the distal straight tubules is associated with the presence of large, translucent, pale yellow to brown, fan-shaped to starburst to globular crystals (Figure 18.4) (Puschner *et al.*, 2007). Crystals are also present in collecting ducts. The presence of these crystals in the more distal tubules, in addition to their morphology, can help to distinguish MCA from calcium oxalate crystals, which are found in the proximal tubules and tend to be smaller with variable shapes and sizes.

## CONCLUSIONS

The vital role that the kidney plays in maintaining homeostasis makes renal injury due to nephrotoxic agents a serious and potentially life-threatening problem. In many instances, prevention of renal injury can be achieved through proper gastrointestinal decontamination and implementation of aggressive intravenous

**FIGURE 18.4** Melamine:cyanurate crystals, canine kidney. Renal tubular epithelium is attenuated and the lumen is expanded by variably sized, fan-shaped to starburst, gray-brown crystals (thick arrow). Another tubule has attenuated epithelium and detached and necrotic cells, proteinaceous fluid and smaller crystals within the lumen (thin arrow). Inflammatory cells are present within the adjacent interstitium. H&E, Bar = 100 μm. (Courtesy of University of California, Davis Anatomic Pathology.).

fluid therapy following exposure to nephrotoxicants. Once renal injury has developed, veterinary intervention is essential in order to support the patient through the acute crisis and to allow time for regeneration and repair of injured renal tissues. Depending on the extent of injury and degree of regeneration, the patient may fully recover, may be left with residual renal insufficiency or may progress to chronic renal failure.

# Reproductive toxicity and endocrine disruption

Tim J. Evans

## INTRODUCTION

Reproduction is a critical biological process in all living systems and is required for species survival. Toxicant-induced abortions, congenital defects and infertility can have devastating effects on livestock production. Wildlife species living in environments contaminated by industrial and/or agricultural chemicals have experienced impaired fertility and declining populations. There is growing concern within the scientific community and among government regulatory agencies about the effects of occupational and environmental exposures to reproductive toxicants on human fertility.

For the purposes of this chapter, the term “reproduction” will be used primarily in reference to vertebrate species of animals (especially mammals) and will be inclusive of “development,” which is sometimes treated as a separate topic in toxicology texts. This particular book chapter will emphasize the interactions between toxicants and the male and female reproductive tracts, as well as xenobiotic-induced effects on the growth, maturation and sexual differentiation of the embryo and fetus. Since “endocrine disruption” is an extremely common mechanism of action for xenobiotics associated with impaired reproductive function, reproductive toxicity and endocrine disruption will be discussed together in this chapter. Efforts will be made to clarify the current terminology related to reproductive toxicity and endocrine disruption and to introduce the reader to normal reproductive anatomy and physiology, as well as important concepts associated with embryonic and fetal development. Endocrine disruption

in wildlife species and humans and the effects of xenobiotics, including endocrine disrupting chemicals (EDCs), on reproductive function in domestic animals will be discussed along with a brief description of proposed mechanisms of action and the effects of some selected reproductive toxicants.

Unfortunately, space constraints limit the amount of information which can be presented in this chapter, and many of the presented topics cannot be discussed at great length. There are a number of recently published textbooks and issues of journals which cover some of these subjects in greater detail and provide information which is complementary to what is presented in this chapter (Burrows and Tyrl, 2001; Plumlee, 2004; Naz, 2005; Golub, 2006a; Hood, 2006; Jobling and Tyler, 2006; Jørgensen *et al.*, 2006b; Mukerjee, 2006; Gupta, 2011). The reader is directed to these publications and other references cited in this chapter in order to gain additional insight into specific areas of reproductive function and toxicology.

It is important that the reader understand that the areas of toxicology involving reproductive toxicity and endocrine disruption, in particular, are in continual flux. New data and exceptions to “classical” mechanisms of action are being reported on a regular basis, and there continues to be ongoing debate about the various aspects of normal as well as xenobiotic-induced abnormal reproductive function. Every effort has been made to accurately represent what is currently understood about the topics of discussion in this chapter. Controversial topics or those currently still subject to debate within the scientific community have been noted wherever possible.

## IMPORTANT DEFINITIONS AND CONCEPTS

### Reproduction

Reproduction in domestic, wild and laboratory vertebrates encompasses the wide range of physiological processes and associated behaviors and anatomical structures involved in the production of the next generation and the survival of a given species of animal (Senger, 2003). The physiological processes involved in reproduction generally include the following: (1) gametogenesis (production of sperm or ova) and the pre- and peri-pubertal changes leading up to its onset; (2) release of gametes (i.e., sperm transport and maturation, penile erection and ejaculation of sperm (mammals), copulation between a male and a female of the same species (several vertebrate classes) and ovulation of oocytes); (3) formation of the zygote (i.e., sperm storage, capacitation and other processes leading to fertilization, or union, of a single sperm with an egg); (4) embryonic and fetal development during the incubation process in egg-bearing vertebrates or, especially in the case of mammals, during pregnancy (gestation) (i.e., activities related to the initiation and progression of zygote cleavage, blastocyst formation, separation of the germ layers, placentation (mammalian species), neurulation and organogenesis (including sexual differentiation)); and finally (5) "birth" of a single or multiple offspring (hatching in oviparous vertebrates). In the conventional sense, the reproductive process culminates with birth or parturition (mammals); however, the initiation and maintenance of milk production (lactation) for the postpartum nutrition of offspring can also be considered a critical aspect of mammalian reproduction (Evans *et al.*, 2007; Evans and Ganjam, 2011).

### Reproductive toxicity

For the purposes of this chapter, "reproductive toxicity" will refer to any manifestations of xenobiotic exposure reflecting adverse effects on the physiological processes and associated behaviors and/or anatomical structures involved in animal reproduction or development. This is a fairly broad definition which encompasses developmental toxicity, as well as any toxic effects of post-pubertal exposures to xenobiotics on either male or female reproduction. "Developmental toxicity" refers to any adverse effect on the developing organism associated with either pre-conception parental exposures to toxicants or post-conception xenobiotic exposures to the embryo, fetus or pre-pubertal offspring (Hodgson *et al.*, 2000; Eaton and Klaassen, 2001; Foster and Gray, 2008). Adverse effects associated with developmental toxicity

of xenobiotics might not necessarily be observed until after the affected individuals have reached sexual maturity (Foster and Gray, 2008; Rogers and Kavlock, 2008).

### Teratogenesis

The term "teratogenesis" is derived from the Greek word for monster ("teras") and is a form of developmental toxicity (Panter, 2002; Rogers and Kavlock, 2008). "Teratogenesis" refers specifically to developmental defects induced by toxicant exposures occurring between conception and birth (Hodgson *et al.*, 2000; Eaton and Klaassen, 2001; Rogers and Kavlock, 2008). The types of abnormalities that are typically associated with teratogenesis include embryonic or fetal death; morphological, functional and/or neurobehavioral abnormalities; and decreased growth rate and/or birth weight (Panter, 2002; Rogers and Kavlock, 2008).

#### *Wilson's general principles of teratology*

With respect to teratogenesis, there are six basic tenets of teratology, first defined by Wilson in 1959, which need to be kept in mind whenever gestational exposure to a teratogenic xenobiotic is suspected or when a chemical is being evaluated for its teratogenic potential. As stated by Wilson in the *Handbook of Teratology* (Wilson, 1977), the general principles of teratology are as follows:

- 1 Susceptibility to teratogenesis depends on the genotype of the conceptus and the manner in which it interacts with environmental factors.
- 2 Susceptibility to teratogenic agents varies with the developmental stage at the time of exposure.
- 3 Teratogenic agents act in specific ways (mechanisms) on developing cells and tissues to initiate abnormal embryogenesis.
- 4 The final manifestations of abnormal development are death, malformation, growth retardation and functional disorder.
- 5 The access of adverse environmental influences to developing tissues depends on the nature of the influences (agent).
- 6 Manifestations of deviant development increase in degree as dosage increases from no effect to the totally lethal level.

#### *Mechanisms of reproductive toxicity and teratogenesis*

There are a wide range of specific mechanisms of action by which xenobiotics can adversely affect reproductive function, including embryonic and fetal development. In general, many of these mechanisms are the same as those for toxicants affecting other organ systems and essentially involve some sort of toxicant-induced cellular dysregulation and alterations in cellular maintenance

which, when possible, the body attempts to repair, either successfully or unsuccessfully (Gregus, 2008). Oxidative damage and interference with normal enzymatic reactions are two common mechanisms by which xenobiotics can cause the dysregulation and altered maintenance of cells within various organs and tissues.

Normal reproduction and development require, by their very nature (see review in this chapter), signaling within and between a variety of diverse organs. In sexual reproduction and mammalian pregnancy, critical communication even takes place between distinctly different organisms (i.e., male and female and mother and offspring, respectively). The dependency of reproductive function on signaling pathways inclusive of gene transcription makes this physiological process especially prone to adverse effects associated with xenobiotic-induced disruption of or interference with cell-to-cell, organ-to-organ and/or even animal-to-animal communication. Many of the mechanisms which interfere with physiological signaling activity can be classified as forms of “endocrine disruption,” which will be discussed in much greater detail in this chapter.

There is a great deal of overlap between the various different mechanisms for reproductive toxicity. The level of exposure to a particular toxicant is an important determinant of what toxic effects are observed. Xenobiotics which “disrupt” endocrine pathways can do so without interactions with endogenous receptors, using mechanisms of action which can cause other forms of toxic insult at various dosages.

### *Reproductive toxicants and teratogens*

Any xenobiotic associated with adverse effects on development or male or female reproductive function can be classified as a “reproductive toxicant.” Xenobiotics capable of inducing teratogenesis are referred to as “teratogens.” Although any chemicals adversely affecting animal well-being have the potential to have a negative impact on development and reproductive function, this chapter will attempt to focus on mechanisms of actions and toxicants which specifically target normal embryonic or fetal growth and maturation or have a direct effect upon the male and/or female reproductive tract.

### **Hormones and hormone receptors**

The term “hormone” classically refers to a substance which is secreted into the circulation by a ductless gland and which alters the function of its target cells (Hodgson *et al.*, 2000). While the traditional “endocrine” aspect of hormone action involves organ-to-organ signaling (and in the case of mammalian pregnancy animal-to-animal signaling), it is recognized that hormones can also be

involved in “paracrine” (cell-to-cell) communication and signaling pathways within the same cell in which they were produced (“autocrine” function) (Evans *et al.*, 2007; Evans and Ganjam, 2011). In vertebrates there are a wide variety of different hormones involved in reproductive function. The major reproductive hormones are generally grouped according to their basic molecular structure and include amino acid derivatives (e.g., dopamine or prolactin inhibitory factor (PIF) and melatonin); peptides (e.g., oxytocin, adrenocorticotropin hormone (ACTH), corticotropin releasing factor or hormone (CRF or CRH), gonadotropin releasing hormone (GnRH) and thyrotropin releasing hormone (TRH)); proteins (e.g., activin, inhibin, insulin-like growth factors, prolactin and relaxin); glycoproteins (e.g., follicle-stimulating hormone (FSH), luteinizing hormone (LH) and thyroid stimulating hormone (TSH or thyrotropin)); steroids (e.g., androgens, estrogens and progestagens); and eicosanoids, which include prostaglandins (Evans *et al.*, 2007; Evans and Ganjam, 2011).

The actions of hormones on their targets are generally mediated through receptors which initiate or inhibit some sort of signal transduction pathway or are required for hormone-induced alterations in gene expression. Hormone–receptor interactions can be modulated by a number of factors including the amount of hormone present, the affinity of the hormone for the receptor, receptor density and occupancy and interaction with other hormones, receptors and hormone–receptor complexes, as well as a variety of endogenous co-activators and inhibitors (Genuth, 2004a; Bigsby *et al.*, 2005). It should be clear by the end of this chapter that various xenobiotics are also capable, under certain exposure conditions, of modulating the interactions between endogenous hormones and their receptors.

### *Gonadal steroid hormones and their “nuclear” receptors*

The primary gonadal steroids (i.e., androgens and estrogens (some references also include progesterone)) are also referred to as the “sex” steroids, and the imitation and/or inhibition of the actions of these hormones by xenobiotics is what was first referred to as “endocrine disruption” (Krimsky, 2000; McLachlan, 2001). The major androgens (testosterone and dihydrotestosterone (5 $\alpha$ -reductase conversion product of testosterone in the testes and selected non-gonadal tissues)), estrogens (estradiol and estrone) and progesterone and endogenous progestagens facilitate the development and regulation of reproductive function in animal species, in large part by interacting with (i.e., functioning as ligands for) receptors which are members of the steroid/thyroid (“nuclear”) receptor superfamily, the largest family of transcription factors in eukaryotic systems (Tsai and O'Malley, 1994; Genuth, 2004a). Receptors in

this superfamily are large oligomeric proteins (Genuth, 2004a), which generally consist of five domains (A/B, C, D, E and F) (Tsai and O'Malley, 1994). Although specific portions of the gonadal steroid nuclear receptor molecules can interact with a variety of co-activators as well as inhibitors, the most important domains of these receptors are generally considered to be those involved in transactivation (*N*-terminal A/B domain; also C-terminus in estrogen receptors (ERs)); DNA-binding and hormone-receptor complex dimerization (middle portion containing two helical zinc fingers; C domain); and hormone (ligand) binding (C-terminus; E domain) (Genuth, 2004a; Bigsby *et al.*, 2005). While androgen, estrogen and progesterone receptors, which are members of the steroid/thyroid superfamily, are often thought of as being exclusively nuclear in their location, these receptors can also be located in the cytoplasm of some cells (Tsai and O'Malley, 1994; Genuth, 2004a). Cytoplasmic and nuclear gonadal steroid receptors can be bound to a variety of different heat shock proteins, which interact with the receptor's hormone-binding domain. Heat shock proteins can act as "blocking" molecules and are displaced by hormones binding to the receptors (Genuth, 2004a; Bigsby *et al.*, 2005) or as "chaperones" involved in receptor turnover and "trafficking" of these receptors between the nucleus and the cytoplasm (Pratt and Toft, 1997).

There is reportedly a single type of androgen receptor which is a member of the steroid/thyroid superfamily. In contrast, there are two types of nuclear ERs (ER $\alpha$  and ER $\beta$ ), which are the products of distinct genes on separate chromosomes (O'Donnell *et al.*, 2001). ER $\alpha$  and ER $\beta$  differ in their amino acid structure, tissue distribution, affinity for selective ER modulators (SERMs) and their role in female (Britt and Findlay, 2002) as well as, somewhat surprisingly, male fertility (O'Donnell *et al.*, 2001; Hess, 2003). The nuclear progesterone receptor also has two isoforms, progesterone receptor A and progesterone receptor B (PRA and PRB, respectively), which differ slightly in their amino acid sequences and their interactions with co-activators. However, unlike ER $\alpha$  and ER $\beta$ , PRA and PRB are the products of a single gene (Brayman *et al.*, 2006).

#### *Genomic and non-genomic mechanisms of action of gonadal steroid hormones*

Traditionally, the receptor-mediated reproductive effects of gonadal steroids were thought to occur almost exclusively through interactions between homodimers of the hormone-nuclear receptor complexes and specific regions of DNA upstream from the basal promoter of a given gene, referred to as hormone-response elements (HREs) or, more specifically, androgen and estrogen-response elements (ARE and ERE, respectively) (Tsai and

O'Malley, 1994; Genuth, 2004a). It is now understood that these "genomic" effects of gonadal steroids and their nuclear receptors, which involve alterations in gene transcription, can, in some instances, involve heterodimers of different nuclear steroid-receptor complexes, indirect binding of hormone-receptor complexes to DNA via proteins within a preformed transcriptional complexes and even ligand (hormone)-independent "activation" of nuclear gonadal steroid receptor molecules (O'Donnell *et al.*, 2001; Bigsby *et al.*, 2005; Thomas and Khan, 2005). In addition, it is also apparent that gonadal steroids can affect cellular function by non-genomic mechanisms of action involving changes in intracellular concentrations of ions, cAMP and its second messengers, and the mitogen-activated protein (MAP) kinase pathway. These non-genomic mechanisms are independent of the somewhat "time-consuming" alterations in gene expression traditionally associated with gonadal steroids and occur rapidly within seconds or minutes (O'Donnell *et al.*, 2001; Thomas and Khan, 2005). While the rapid, non-genomic effects of gonadal steroids most likely involve receptors bound to the plasma membrane, the specific identity and classification of these receptors remain unclear and might involve a number of different receptor types (Razandi *et al.*, 1999; O'Donnell *et al.*, 2001; Thomas and Khan, 2005; Warner and Gustafsson, 2006).

#### **Endocrine disruption**

"Endocrine disruption" is a developing, multidisciplinary area of research, involving aspects of both toxicology and endocrinology (McLachlan, 2001). "Endocrine disruption" is also a potential mechanism of action for many toxicants, and this term has been defined in a variety of different ways, depending on the circumstances and the intended audience. Some of these definitions can be fairly "broad," such as the one which will be used in this chapter (see below). However, "endocrine disruption" can also be defined fairly narrowly with respect to toxicant origin (synthetic versus naturally occurring); source or site of toxicant exposure (environmental contamination versus occupational exposure); xenobiotic mechanism of action (receptor agonism and/or antagonism (see definition below) versus other mechanisms independent of direct interactions between xenobiotics and receptors); and/or the timing of exposure (prenatal versus postnatal exposures) (Krimsky, 2000, 2001). It is critically important for one to carefully define the context in which "endocrine disruption" is being used in order to clearly and accurately discuss one's research findings or opinions with toxicologists, physiologists, wildlife biologists, medical professionals, regulatory personnel, the popular press and/or the general public (McLachlan, 2001).

Although the imitation and/or inhibition of the actions of androgens and, especially, estrogens by xenobiotics is what was first referred to as “endocrine disruption,” both the multidisciplinary area of study and mechanism of action generally referred to as “endocrine disruption” have evolved over the years to encompass a wide range of specific mechanisms of action which can ultimately result in adverse effects on invertebrate and/or vertebrate animals (McLachlan, 2001). As scientists continue to investigate the effects of xenobiotics on biological systems, the paradigm of endocrine disruption will continue to “shift,” and a willingness to “step out of the box” and discuss endocrine disruption in a broader context will be necessary in order to participate in scientific discussions, to design future experiments and/or to make informed, medical or policy decisions based on “good” science (McLachlan, 2001; Guillette, 2006). For the purposes of this chapter “endocrine disruption” will refer to the effects of any synthetic or naturally occurring xenobiotic which can affect the endocrine system of exposed individuals (i.e., the balance of normal hormonal functions) and, as a result of exposure, cause physiological alterations (Keith, 1997; Hodgson *et al.*, 2000). Within the broad scope of this definition, reproduction, including prenatal and pre-pubertal development, certainly would be expected to be one of the physiological functions most profoundly affected by chemicals capable of endocrine disruption. In fact, it could be argued that the majority of reproductive toxicants interfere with endocrine function in one way or another. However, adverse effects on other, “non-reproductive” endocrine systems can also be associated with exposures to xenobiotics, and these “non-reproductive” effects need to be taken into consideration as well when describing the endocrine disruption associated with exposure to a given chemical (Guillette, 2006).

### ***Mechanisms of endocrine disruption***

Endocrine disruption encompasses a wide range of mechanisms of action which can ultimately result in adverse effects on animal species. The mechanisms of action involved in endocrine disruption can include effects which are mediated directly by interactions between the xenobiotic and an endogenous hormone receptor (i.e., the xenobiotic functions as a ligand for an endogenous receptor and a receptor–ligand complex is formed), as well as those adverse effects which alter hormonal functions without direct interactions between the toxicant and an endogenous receptor (Keith, 1997). In addition, it should be noted that some xenobiotics are capable of causing endocrine disruption by functioning as an endogenous hormone receptor ligand, as well as by mechanisms of action which are independent of the formation of a xenobiotic (ligand)–receptor complex.

### ***“Classic” receptor-mediated endocrine disruption***

“Classic” endocrine disruption can involve imitation or mimicry of the interactions between cellular receptors and endogenous hormones (i.e., receptor agonism) and/or a blockade or inhibition of the formation of receptor–hormone complexes (i.e., receptor antagonism) (McLachlan, 2001). With respect to gonadal steroids, both genomic and non-genomic physiological responses can be affected by this mimicry or blockade of endogenous hormone receptor-mediated activity (Thomas and Khan, 2005). Xenobiotics which mimic the actions of endogenous androgens or estrogens (i.e., gonadal steroid receptor agonists) are referred to, respectively, as being either “xenoandrogens” or “xenoestrogens.” Conversely, reproductive toxicants which inhibit or block endogenous estrogens or androgens from interacting with their respective receptors (i.e., gonadal receptor antagonists) are generally classified as “antiandrogens” or “antiestrogens.” Progestagens (“progestogens” or “progestins” in some literature) is a generic term for endogenous or synthetic compounds which interact with progesterone receptors, and there is evidence of increasing environmental contamination with these types of EDCs.

Some xenobiotics can act as receptor agonists or antagonists, depending on the circumstances or tissues involved. “Selective ER modulators” or “SERMs” refer to a class of xenobiotics which, although originally classified as antiestrogens, can function as either ER agonists or antagonists, depending on the tissue in which estrogen-dependent responses are being discussed (Dutertre and Smith, 2000; Katzenellenbogen and Katzenellenbogen, 2000). SERMs are particularly relevant with respect to observed differences in their binding affinities to ER $\alpha$  or ER $\beta$  and their development as therapeutic agents for different types of estrogen-responsive neoplasia.

### ***Endocrine disruption independent of receptor-mediated interactions***

Endocrine disruption which is independent of interactions between xenobiotics and endogenous hormone receptors can occur in a variety of different ways. Xenobiotic exposure can result in alterations in the number of hormone receptor sites (up- or down-regulation) or can cause direct or indirect hormone modifications which alter hormonal function (Keith, 1997). Xenobiotics can change the rate of synthesis or destruction of endogenous hormones and can alter how hormones are stored, how they are released into and/or transported within the circulation or even how they are eventually cleared from the body (Keith, 1997; Sikka *et al.*, 2005). Any xenobiotic which is toxic to organs or tissues producing hormones (e.g., testis and ovary) has the potential to decrease hormone synthesis and thereby indirectly cause endocrine disruption (Devine and Hoyer, 2005). It should also be noted that some of these

mechanisms of endocrine disruption are not necessarily exclusive of one another. A given xenobiotic can potentially disrupt the normal balance of hormonal function by more than one mechanism which is independent of direct interactions between the toxicant and an endogenous hormone receptor.

#### ***“Androgenic” and “estrogenic” effects of xenobiotics***

The terms “androgenic” and “estrogenic” and their antonyms “antiandrogenic” and “antiestrogenic” have been used in a number of different contexts. Some authors have used these terms to refer specifically to the agonistic and antagonistic receptor interactions of xenobiotics (Hodgson *et al.*, 2000). Because the precise mechanism of endocrine disruption of a given toxicant might not always be known or might involve multiple mechanisms of action, these terms have also been used in a more general sense, especially in livestock and wild-life species, to refer to phenotypic changes which were similar to or the opposite of the effects which would be expected with exposure to endogenous androgens or estrogens (Guillette, 2006). This type of general usage can be helpful in some instances but can also be confusing, given that xenoandrogens and progestagens frequently have the opposite phenotypic effects as xenoestrogens. For instance, the effects of estrogenic xenobiotics can be described as antiandrogenic or anti-progestagenic in some instances, while the effects of xenoandrogens and progestagens can be referred to as being antiestrogenic in nature. Further confusion can be associated with exposures to mixtures of chemicals having different phenotypic effects, as is often the case in instances of environmental contamination, or with exposures to xenobiotics having mixed antiestrogenic and antiandrogenic effects (i.e., methoxychlor). When the terms “androgenic,” “estrogenic” or their antonyms are used within this chapter, an attempt will be made to clearly denote the intended specific or general meaning of the terms in the context in which they are used. The discretionary use of the terms “feminization” and “masculinization,” as well as “defeminization” and “demasculinization,” can also, in some instances, help to clarify and/or describe the phenotypic effects of a chemical suspected of endocrine disruption.

#### ***Endocrine disrupting chemicals, endocrine disruptors and hormonally active agents***

Any reproductive toxicant capable of endocrine disruption can be considered an “EDC” or an “endocrine disruptor.” Obviously, this includes a large number of xenobiotics which are used in commercially available industrial, agricultural and pharmaceutical products, as well as naturally occurring toxicants produced by plants and fungi. An effort will be made later in this chapter to

discuss some of the xenobiotics most often associated with endocrine disrupting mechanisms of action.

Another term frequently used with respect to endocrine disruption, especially regarding xenobiotics which interact with endogenous hormone receptors, is “hormonally active agent” or “HAA.” In most instances, “endocrine disrupting chemical,” “endocrine disruptor” or “hormonally active agent” can be used interchangeably to discuss the actions of a given xenobiotic. However, whereas “endocrine disrupting chemical” and “endocrine disruptor” generally have negative connotations and imply, by virtue of the inclusion of the term “disrupt,” something “dangerous” and the likelihood of adverse or toxic effects, the term “hormonally active agent” is more benign and only indicates that a given xenobiotic has the potential to affect a hormonal pathway in an animal (Krimsky, 2001). As pointed out by Krimsky (2001), a mechanism rather than a specific pathology is inferred by “hormonally active,” and “hormonally active agent” is the nomenclature preferred by the National Research Council (Knobil, 1999), especially when referring to xenobiotics which interact with endogenous hormone receptors.

The circumstances and intended audience will often dictate the terms used to describe xenobiotics associated with or suspected of being having endocrine activity. “Environmental hormone” and “environmental signal” have also been used, along with “HAA,” “EDC” and endocrine disruptor, to describe xenobiotics capable of interacting with endogenous hormone receptors (McLachlan, 2001; McLachlan *et al.*, 2006). However, the context in which these two terms have been routinely used generally implies environmental contaminants with documented adverse endocrine effects on animals or humans. In some instances, the term “HAA” might be more “politically correct” (Krimsky, 2001) than “EDC,” “endocrine disruptor,” “environmental hormone” or “environmental signal” when discussing chemicals with a suspected hormonal activity that has not been clearly associated with adverse effects on animals in a research and/or clinical setting.

#### ***Aryl hydrocarbon receptor-mediated endocrine disruption***

Endocrine disruption mediated by the aryl hydrocarbon receptor (AhR) is a relatively complex, species- and tissue-dependent phenomenon, involving several of the previously described mechanisms of EDC action and interactions with many important, environmentally persistent compounds. Some aspects of AhR-mediated endocrine disruption are reminiscent of the ligand-induced transcription associated with gonadal steroid receptor function. However, the unique nature of the endogenous AhR and its interactions with primarily xenobiotic agonists warrants further discussion.

### *Aryl hydrocarbon receptor agonists*

The major agonists for the AhR protein belong to the class of environmental contaminants referred to collectively as “halogenated” or “polyhalogenated aromatic hydrocarbons” (HAHs or PAHs, respectively) and includes many highly stable and lipophilic organochlorine industrial chemicals (e.g., polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzodifurans (PCDFs)), as well as their metabolites (Safe, 2005). In addition, other organic compounds, such as polycyclic aromatic hydrocarbons (PAHs) (e.g., 3-methylcholanthrene and benzo[a]pyrene) (BaP)) and flavones (e.g.,  $\beta$ -naphthoflavone), have also been shown to be AhR agonists (Parkinson and Ogilvie, 2008).

### *Mechanisms of aryl hydrocarbon receptor-mediated endocrine disruption*

Many of the mechanisms of action mediated by AhR–ligand interactions have been elucidated using 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) as a prototypical AhR agonist (Safe, 2005; Parkinson and Ogilvie, 2008). TCDD is considered by many to be the most toxic of all of the HAHs, and it is reported to have the highest AhR-binding affinity of any of the xenobiotics in that class of chemicals (Safe, 2005). The AhR, also referred to as the “dioxin receptor,” is located in the cytoplasm bound to heat shock proteins (Parkinson and Ogilvie, 2008). Following ligand (i.e., TCDD) binding and the subsequent disassociation of the heat shock proteins, the AhR is activated by phosphorylation (Parkinson and Ogilvie, 2008) and the activated ligand–AhR complex undergoes a rapid sequence of events involving interactions with the AhR nuclear translocator protein (Arnt) and relocation of the ligand–AhR–Arnt complex into the nucleus (Safe, 2005).

Within the nucleus, the liganded AhR/Arnt heterodimer can facilitate a variety of endocrine disrupting mechanisms. This activated heterodimer complex can interact with dioxin/xenobiotic-response elements (DREs/XREs), which function in much the same way as the previously discussed HREs, and with various co-activators to increase the expression of selected genes (Safe, 2005; Parkinson and Ogilvie, 2008). Depending on the animal species and the tissue, multiple-phase I drug-metabolizing enzymes (e.g., cytochrome P450 (CYP) enzymes (CYP1A1, CYP1A2 and CYP1B1)) and enzymes involved in phase II drug-biotransformation reactions (e.g., glutathione-*S*-transferase and glucuronosyl transferase), are induced by TCDD (Safe, 2005).

Although the antiandrogenic and antiestrogenic properties of TCDD have been associated with the ability of HAHs to induce enzymes involved in androgen and estrogen metabolism, TCDD can interact with

androgen-, estrogen- and progestagen-modulated pathways in a number of ways, including interference with neuroendocrine development (Petersen *et al.*, 2006). AhR-mediated effects of TCDD can interfere with the biosynthesis of testosterone by a mechanism which alters the regulation of the synthesis and release of LH (Sikka *et al.*, 2005). It has also been shown in cell cultures that TCDD can disrupt testosterone signal transduction pathways (Jana *et al.*, 1999). The liganded AhR/Arnt heterodimer appears to be able to interact with inhibitory DREs (iDREs) in selected tissues to suppress the expression of some genes induced by estrogens (Safe, 2005), as well as be able to actually block the ability of estrogen–ER complexes to bind to their HREs (Kharat and Saatcioglu, 1996; Thomas and Khan, 2005). It is likely that a variety of other means of crosstalk between TCDD- and estrogen-mediated signaling pathways exist, and, in fact, TCDD has actually been shown to have the potential for estrogenic activity through interactions between liganded AhR/Arnt heterodimers and unliganded ERs (both ER $\alpha$  and ER $\beta$ ) (Ohtake *et al.*, 2003; Bigsby *et al.*, 2005; Thomas and Khan, 2005). Ohtake *et al.* (2003) have reported that these novel interactions resulted in the recruitment of unliganded ERs and p300 co-activator to gene promoters which are responsive to estrogens. Based on the results of the various experiments performed with TCDD, it is important to remember that the effects observed following exposure to HAHs and EDCs, in general, can be dependent on animal species involved, as well as the type of tissue, organ or physiological response being evaluated.

### *Epigenetic mechanisms of action of endocrine disrupting chemicals*

In recent years there has been increasing interest in the association between prenatal exposures to some reproductive toxicants and the postnatal development of neoplasia (cancer) involving the reproductive tract, as well as the occurrence of transgenerational or vertically transmitted adverse reproductive effects (Crews and McLachlan, 2006). These two phenomena are not mutually exclusive of one another, and, in fact, there is increasing evidence of vertically transmitted neoplasia involving reproductive organs (McLachlan *et al.*, 2006). Both tumor formation and transgenerational reproductive abnormalities can occur because of “genetic” mutations or alterations in the genotype (i.e., DNA sequence) or as a result of “epigenetic” changes where there are heritable modifications in the properties of a cell which do not represent genetic changes (inherited phenotypic alteration without genotypic change) (Lewin, 1998; McLachlan, 2001; Crews and McLachlan, 2006).

Epigenetic changes are a normal part of development and most likely represent one means for heritable

environmental adaptation (Crews and McLachlan, 2006). One of the more common mechanisms of epigenetic modification in mammals is DNA methylation of CpG nucleotides in the promoter regions of genes, which results in methylated genes being “turned off” and unmethylated or demethylated genes being “turned on” (McLachlan, 2001; Anway and Skinner, 2006). Patterns of DNA methylation are generally established during development at the gastrulation stage (i.e., lineage-specific pattern in somatic cells) and after sex determination (i.e., germ line-specific lineage pattern in the gonad) (Anway and Skinner, 2006). DNA methylation can facilitate “genomic imprinting,” a form of epigenetic gene regulation resulting in the expression of the allele from only one parent (i.e., monoallelic expression) (McLachlan, 2001; Anway and Skinner, 2006). The ability of developmental exposures to xenobiotics to provide a basis for adult disease, such as neoplasia, might very likely involve epigenetic changes involving methylation or demethylation of the promoters for specific genes (Newbold *et al.*, 2006). Epigenetic modification by alterations in DNA methylation patterns in the germ line might be one mechanism for observed xenobiotic-induced transgenerational (vertically transmitted) effects associated with infertility and tumor susceptibility in rodents (Anway and Skinner, 2006; Newbold *et al.*, 2006).

#### *Disruption of “non-reproductive” endocrine systems*

Although it can be argued that almost all endocrine systems are “reproductive” to some extent, there are multiple systems with primary functions which are not directly related to reproduction, and several of these systems have also been identified as potential targets of EDCs. In addition, gonadal steroids and xenobiotics which mimic these endogenous hormones can have “non-reproductive” effects. The synthesis of triiodothyronine (T<sub>3</sub>) and thyroxine (T<sub>4</sub>) by the thyroid gland can be decreased by chemicals which inhibit the uptake of iodine (e.g., perchlorate and thiocyanate) and also by xenobiotics which inhibit thyroperoxidase (e.g., thiourea, propylthiourea (PTU), some sulfonamides, methimazole, carbimazole, aminotriazole and acetoacetamide) (Capen, 2008). Polybrominated diphenyl ethers (PBDEs) have been shown to have antithyroidal activity (Guillette, 2006), and thyroid hormone secretion can be inhibited by exposure to excessive amounts of iodine or lithium (Capen, 2008). Xenobiotics, such as the *o,p'*-DDD metabolite of dichlorodiphenyltrichloroethane (DDT), can interfere with glucocorticoid metabolism (Guillette, 2006), and there has been increasing interest in the relationship between gestational and neonatal exposures to xenoestrogens and the development of obesity (Cooke and Naz, 2005; Newbold *et al.*, 2005, 2006). Some EDCs (e.g., organotin compounds) have recently been described as “obesogens”

because of their ability to affect adipogenesis by several different mechanisms, including interactions involving the isoforms of 11 $\beta$ -hydroxysteroid dehydrogenase (11 $\beta$ -HSD) which play key roles in glucocorticoid metabolism (Grün and Blumberg, 2006). Because of increased societal concerns about obesity, there is likely to be greater future interest in organotins and other EDCs with similar “obesogenic” activities.

## NORMAL ANIMAL REPRODUCTION

Reproduction is a complex and dynamic process involving precise coordination and integration of the functions of multiple organs within the body. The production of viable and functional gametes and their transport and union to form a zygote which develops into a healthy and fertile individual require that many stringent physiological and metabolic needs be met. A thorough understanding of the mechanisms involved in reproduction is absolutely essential in order to recognize which steps in the reproductive process are most susceptible to the adverse effects of potential toxicants. It is critical that one be able to understand the pathophysiological basis for reproductive abnormalities. In addition, it is necessary, from a clinical perspective, to identify what constitutes “normal” reproduction in order to recognize abnormal reproductive behaviors and morphological changes in both domestic and wild animals. Impaired reproductive function in domestic animals, which is associated with exposure to toxic amounts of xenobiotics, necessitates the use of diagnostic, prognostic and therapeutic procedures which require a thorough knowledge of normal reproductive anatomy and physiology.

Normal reproduction will be reviewed in this chapter to provide a basis for discussion concerning specific reproductive toxicants. Although the emphasis will be on mammalian reproduction, many of the principles will be applicable to other classes of vertebrates. If additional information is needed, textbooks are available which provide a comprehensive overview of animal reproduction (Hafez and Hafez, 2000; Senger, 2003), as well as general veterinary anatomy (Dyce *et al.*, 2002). Other references can be consulted for descriptions of various aspects of normal reproduction in species of domestic or laboratory animals, which might be of particular interest to the reader (Johnston *et al.*, 2002; Hedrich and Bullock, 2004; Suckow *et al.*, 2006; Youngquist and Threlfall, 2007).

### Neuroendocrine control of reproduction

In humans and animals alike, visual, olfactory, auditory and other sensory data are integrated within the brain

and are reflected in endocrine events. The neuroendocrine functions of the pineal gland, hypothalamus and pituitary gland play an important role in the integration and endocrine regulation of the body's physiological processes and are potential targets for many reproductive toxicants (i.e., dioxins). These structures within the brain and proper function of the hypothalamic-pituitary-gonadal axis facilitate development of the reproductive tract and endocrine regulation of spermatogenesis in the male and the estrous or menstrual cycle in the female. The onset of puberty and sexual behavior in males and females, the ability to achieve erection and ejaculation in males, and the normal progression of gestation, parturition and lactation in females are all affected by the secretions of the hypothalamus and pituitary gland, as well as interactions between these structures and the reproductive tract (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011).

The hormones involved in the neuroendocrine control of reproduction are produced in several regions of the brain. Melatonin is produced in the pineal gland. The major hormones of reproductive interest which are of hypothalamic origin are dopamine, CRF, GnRH and TRH. Oxytocin is released from the posterior pituitary (neurohypophysis), and ACTH, FSH, LH, prolactin and TSH are synthesized and released from the anterior pituitary (adenohypophysis) (Ginther, 1992; Evans *et al.*, 2007; Evans and Ganjam, 2011). The production and release of these hormones are regulated by various positive and negative feedback loops, which are potentially susceptible to the effects of hormonally active xenobiotics.

## Puberty

### *The onset of puberty*

Puberty in male and female offspring implies reproductive competence and corresponds to the onset of normal spermatogenesis in the male and reproductive cyclicity in the female. Puberty can be indicated in the female by the age at first estrus or ovulation or even the age at which pregnancy can be maintained safely (Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011). In the male, the age at the time of preputial separation and the acquisition of the ability to ejaculate or the age at the first appearance of spermatozoa in the ejaculate or urine, as well as the production of threshold concentrations of fertile sperm in the ejaculate, have all been used as indicators of puberty (Senger, 2003). Species, nutritional status, environmental and social factors, pheromones and photoperiod in short- or long-day breeders can all influence the age of onset of puberty in animal species (Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011).

### *The endocrinology of puberty*

From an endocrine perspective, puberty is associated with the ability of the hypothalamus to release enough GnRH to induce gonadotropin production by the anterior pituitary gland (Senger, 2003). This endocrine milestone is brought about by the postnatal developmental changes which allow the hypothalamus to overcome the negative feedback of testicular androgens and estrogens in males and which facilitate the ovary's ability to produce sufficient estrogens to induce the preovulatory surge of GnRH in females (Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011). Many of the endocrine changes which come into play with the onset of puberty are also involved in the transition from anestrus to the ovulatory season in seasonally polyestrous female animals (Evans *et al.*, 2007; Evans and Ganjam, 2011).

### *The susceptibility of the pubertal process to reproductive toxicants*

While puberty is often described simply in terms of a single, initial reproductive event (e.g., first estrus, ovulation or ejaculation), the attainment of reproductive competency is actually a process which is susceptible to the effects of reproductive toxicants. Xenobiotics can interfere with important physiological and morphological transformations necessary for the normal stepwise progression toward reproductive competency. Pre-pubertal follicular development, as well as the onset of the preovulatory LH surge in the female and the transition in testicular estrogen synthesis from the Sertoli cell to the Leydig cell in the males of many species, in addition to the postnatal proliferation of Sertoli cells in some mammals, are all potentially susceptible to the adverse effects of xenobiotics. Pre- or peri-pubertal exposure to hormonally active xenobiotics, such as anabolic steroids and antiandrogens, can interfere with postnatal reproductive development and function and can impair an animal's ability to reach its maximum reproductive potential (Monosson *et al.*, 1999; Evans *et al.*, 2007; Evans, 2011a; Evans and Ganjam, 2011).

## Normal male reproductive anatomy and physiology

### *Reproductive anatomy of the male*

Anatomical structures associated with reproduction in the male usually include, especially in mammals, paired testes (male gonads) positioned outside the abdominal cavity in most species; an excurrent duct system (i.e., efferent ductules, paired epididymides, vas deferens and urethra); accessory sex glands (i.e., ampullae, seminal vesicles, prostate and bulbourethral glands); a

scrotum and its associated thermoregulatory functions to protect the testes from mechanical and thermal insult and some form of copulatory organ or penis with a mechanism for protrusion, erection, emission of glandular secretions and ejaculation of sperm. The primary functions of the testis (testicle) are spermatogenesis (production of male gametes (sperm or spermatozoa)) and steroidogenesis (production of androgens and estrogens). Unlike the female in which oögonia are no longer replicating and the full complement of potential oocytes are present at birth, spermatogonia are proliferating and differentiating into spermatozoa continuously, and the testis is organized in such a way as to maximize sperm production (Senger, 2003; Evans and Ganjam, 2011).

#### *Testicular structure*

The parenchyma of the testis is divided into the tubular and interstitial compartments (Senger, 2003; Evans and Ganjam, 2011) (Figure 19.1a). The structural and functional units of the testis are the seminiferous tubules within the tubular compartment and the Leydig (interstitial cells) within the interstitial compartment. Depending on the species, it is estimated that the seminiferous tubules comprise approximately 80% of the adult testis, with the interstitium comprising most of the remaining 20% (Genuth, 2004b). Seminiferous tubules form highly convoluted loops (tubulus contortus) which begin and end with straight portions (tubulus rectus) that connect to the rete tubules (Thomas and Thomas, 2001; Genuth, 2004b; Senger, 2003; Evans and Ganjam, 2011). In some species, the rete tubules coalesce in a fibrous region of the testis referred to as the mediastinum, which joins with septal projections of the tunica albuginea, part of the testicular capsule (Senger, 2003). The rete tubules join with the efferent ductules which attach to the epididymidis.

Within the seminiferous tubules are germ cells at various stages of differentiation and Sertoli cells which provide germ cells with structural support and nutrients, as well as regulatory and paracrine factors (Thomas and Thomas, 2001) (Figure 19.1b). Tight junctions (junctional complexes) between adjacent Sertoli cells divide the seminiferous epithelium into basal and adluminal compartments, with Sertoli cells anchored to the basement membrane and surrounding the developing populations of germ cells (Thomas and Thomas, 2001; Genuth, 2004b; Senger, 2003; Evans and Ganjam, 2011). The seminiferous tubules are surrounded by peritubular myoid cells, which in combination with the junctional complexes, form the “blood–testis barrier” to prevent free exchange of large proteins and some xenobiotics between the blood and the fluid within the seminiferous tubules (Thomas and Thomas, 2001; Senger, 2003; Evans and Ganjam, 2011).

Within the interstitial compartment are the Leydig (interstitial) cells, as well as capillaries, lymphatic vessels and connective tissue (Senger, 2003; Evans and Ganjam, 2011). The Leydig cells are homologous to the theca interna cells in the ovary and produce testosterone (also estrogen in some species). There are species differences with respect to the abundance of Leydig cells in the interstitium, and these differences are important to recognize when reporting Leydig or interstitial cell hyperplasia in response to toxicant exposure. It should also be noted that Leydig and, to a lesser extent, Sertoli cells contain enzymes involved in xenobiotic biotransformation, and the synthesis of toxic metabolites can actually occur within the testis, in close proximity to the target cells for a given reproductive toxicant (Thomas and Thomas, 2001; Haschek *et al.*, 2010).

#### *Excurrent duct system*

The excurrent duct system consists of the efferent ductules, the epididymal duct and the ductus deferens. This duct system functions to conduct spermatozoa, rete fluid and some testicular secretory products away from the testis and eventually into the pelvic urethra (Senger, 2003; Evans and Ganjam, 2011). The reabsorption of fluid by a species-variable number of efferent ductules is essential for normal testicular function (O'Donnell *et al.*, 2001; Hess, 2003), and these tubules terminate by joining a single highly coiled epididymal duct, commonly referred to as the epididymidis or epididymis. Depending on the species, the epididymidis is generally subdivided into the initial segment, head (caput), body (corpus) and tail (cauda), with the various portions sometimes being further subdivided (França *et al.*, 2005). The primary functions of the epididymidis are transport and sustenance of sperm, reabsorption and secretion of fluid (initial segment and head, respectively); spermatozoal acquisition of motility and fertile potential (i.e., sperm maturation); recognition and elimination of defective spermatozoa; sperm storage prior to ejaculation and secretory contributions to the seminal fluid (Sutovsky *et al.*, 2001). The epididymal transit time varies somewhat with species, but is generally approximately 7 to 14 days in length, depending on several factors including ejaculation frequency. The ductus deferens conducts spermatozoa matured in the epididymidis to the pelvic urethra which helps to form the penis.

#### *Accessory sex glands*

There are a number of accessory sex glands (the complement of which varies with species) that contribute to the composition of the seminal fluid in mammals. These glands include the ampullae, seminal vesicles (vesicular glands), prostate and bulbourethral glands (Senger, 2003; Evans and Ganjam, 2011). Laboratory rodents (i.e., mice

**FIGURE 19.1** Loops of the seminiferous tubules, rete testis and excurrent duct system (i.e., efferent ductules (vas efferentia), epididymis (epididymis) and ductus deferens (vas deferens)), as well as a cross-section of a seminiferous tubule showing the microanatomy of the seminiferous epithelium in a “typical” mammalian testis, are shown in (A). Mature spermatozoa follow the pathway denoted by arrows. Testicular fluid is secreted by the Sertoli cell into the lumen of the seminiferous tubule. The portion of the testicular parenchyma outside of the seminiferous tubules is the interstitium. The predominant cell type within the interstitium is the Leydig or interstitial cell. The complex nature of the association between Sertoli cells and developing germ cells within the seminiferous epithelium in a “typical” mammalian testis is shown in (B). The Sertoli cell and germ cells are shown schematically disassociated to demonstrate how spermatozoal precursors occupy spaces between adjacent Sertoli cells. Spermatogonia, spermatocytes, round spermatids and elongate spermatids are denoted by Sg, Sc, RSt and Est, respectively. This figure was adapted, with permission, from [Garner DL, Hafez ESE \(2000\)](#) (modifications and artwork courtesy of Don Connor and Howard Wilson).

and rats) have an additional gland referred to as the preputial gland, which appears to have a role in the production of pheromone ([Haschek et al., 2010](#)). These accessory sex glands in the male are generally considered to be androgen dependent, with conversion of testosterone to DHT occurring in the prostate and seminal vesicles of many species ([Senger, 2003; Haschek et al., 2010; Evans and Ganjam, 2011](#)). The weights of the accessory sex glands can be used as an indirect measure of testosterone concentrations or exposure to antiandrogens ([Thomas and Thomas, 2001; Senger, 2003; Evans and Ganjam, 2011](#)).

#### External genitalia

The external genitalia of the male consist of the copulatory organ or penis, the prepuce, which protects the penis from environmental and mechanical injury, and the scrotum for testes positioned outside of the abdominal cavity. Penile structure is extremely species variable, with some species even having a special penile bone (i.e., os penis), but the shaft of the penis generally consists of erectile tissue (corpus cavernosum and corpus spongiosum) which surrounds the pelvic urethra. The glans penis is homologous to the female clitoris, and stimulation of the glans is the primary factor involved

in the initiation of ejaculation ([Senger, 2003; Evans and Ganjam, 2011](#)). The scrotum protects the testes from mechanical injury and, in conjunction with the tunica dartos, cremaster muscle and pampiniform plexus, plays a major thermoregulatory role with respect to temperature-sensitive, testicular spermatogenesis. In some species of wildlife (e.g., elephants and marine mammals), the testes are positioned intra-abdominally. Xenobiotics, which cause hyperthermia (i.e., ergopeptine alkaloids) or which induce fever, have the potential to adversely affect spermatogenesis.

#### Spermatogenesis

Spermatozoa are highly specialized haploid cells equipped with a self-powered flagellum to facilitate motility, as well as an acrosome to mediate penetration of the zona pellucida. Spermatogenesis takes place within the seminiferous tubules and consists of all the changes germ cells undergo in the seminiferous epithelium in order to produce adequate numbers of viable spermatozoa each day and to continuously replace spermatogonial stem cells ([Thomas and Thomas, 2001; Senger, 2003; Evans and Ganjam, 2011](#)). Spermatogenesis provides for genetic diversity and ensures that germ cells are in an immunologically favored site ([Senger,](#)

2003; Evans and Ganjam, 2011). The duration of spermatogenesis varies with species but generally ranges between 4 and 8 weeks (approximately 30–60 days) in domestic and laboratory animals and is approximately 75 days (almost 11 weeks) in humans. It is important to keep in mind the durations of spermatogenesis and epididymal sperm transport in a given species, as well as the normal, species-specific number of spermatozoa produced daily by the testes, when determining the period of toxicant exposure relative to the appearance of abnormal spermatozoa in an ejaculate and when assessing the severity and reversibility of toxicant-induced damage to sperm precursors within the testes.

Spermatogenesis can be subdivided into three phases or stages referred to as “proliferation,” “meiosis” and “differentiation.” During each of these phases, sperm precursors or male germ cells (spermatogonia, spermatocytes or spermatids) undergo specific, stepwise changes as they develop into spermatozoa which will eventually be released into the excurrent duct system. Each of these phases involves a different type of germ cell undergoing a different developmental process, and, as such, these phases have the potential to differ in their susceptibility to the mechanisms of action of various reproductive toxicants.

#### *Proliferation (mitosis or spermatocytogenesis)*

The “proliferation” phase of spermatogenesis has also been referred to as “mitosis” or “spermatocytogenesis” and occurs within the basal compartment of the seminiferous tubule. Proliferation denotes all of the mitotic divisions involving spermatogonia (Senger, 2003; Evans and Ganjam, 2011). A large number of B-spermatogonia result from the mitoses of several generations of spermatogonia (e.g., A<sub>1</sub>, A<sub>2</sub>, A<sub>3</sub>, A<sub>4</sub> and I; some species variations in nomenclature) (Senger, 2003; Genuth, 2004b; Evans and Ganjam, 2011). Stem cell renewal is accomplished during proliferation by the reversion of some spermatogonia to more primitive germ cells (Senger, 2003; Evans and Ganjam, 2011). Germ cell mitosis during spermatogenesis ends with the transformation of B-spermatogonia into primary spermatocytes, and this process is particularly susceptible to toxicants, such as chemotherapeutic agents and radiation, which target rapidly dividing cells.

#### *Meiosis*

“Meiosis” takes place within the adluminal compartment of the seminiferous tubules and involves the participation of primary and secondary spermatocytes in a total of two meiotic divisions. The chromosomal reduction, synapsis and crossover, as well as cellular division and separation, which occur during this phase of spermatogenesis, are extremely complex and guarantee

genetic diversity (Senger, 2003; Genuth, 2004b; Evans and Ganjam, 2011). The meiosis phase of spermatogenesis is considered by some to be most susceptible to toxic insult (Thomas and Thomas, 2001) and ends with the production of haploid round spermatids (Senger, 2003; Evans and Ganjam, 2011).

#### *Differentiation (spermiogenesis)*

Spermatozoa have been aptly characterized as “sophisticated, self-propelled packages of DNA and enzymes” (Senger, 2003; Evans and Ganjam, 2011). “Differentiation” or “spermiogenesis” involves all the changes occurring within the adluminal compartment, which transform round spermatids into spermatozoa possessing an acrosome for penetration of the zona pellucida and a tail or flagellum to facilitate motility (Genuth, 2004b). Differentiation can be subdivided into the “Golgi,” “cap,” “acrosomal” and “maturation” phases, which correspond respectively to acrosomal vesicle formation; spreading of the acrosomal vesicle over the nucleus; elongation of the nucleus and cytoplasm and final assembly involving the formation of the post nuclear cap organization of the tail components (Senger, 2003; Evans and Ganjam, 2011). Following the nuclear and cytoplasmic reorganization which characterizes the changes to germ cells during spermiogenesis, differentiated spermatozoa are released from Sertoli cells into the lumen of the seminiferous tubules by a process referred to as “spermiation.” The complex signaling pathways and genomic imprinting involved in regulating the differentiation of round spermatids into spermatozoa are potential targets for EDCs.

#### *The cycle of the seminiferous epithelium*

In most sexually mature mammals, spermatozoa are produced continuously, with the entry of germ cells into the proliferation phase of spermatogenesis occurring in a coordinated cyclic manner (Genuth, 2004b). Spermatogonia A in a given region of the seminiferous tubule commit to proliferate in a synchronous manner, with cohorts of their progeny germ cells (cellular generations) connected by intercellular bridges and developing and differentiating in unison (Thomas and Thomas, 2001; Senger, 2003; Evans and Ganjam, 2011). Including spermatogonia A, four or five generations or concentric layers of sperm precursors are present in each cross-section of the seminiferous tubules (Figure 19.1) (Thomas and Thomas, 2001; Senger, 2003; Haschek *et al.*, 2010; Evans and Ganjam, 2011). The cycle of the seminiferous epithelium in most mammals is characterized by germ cells in each spermatogenic phase associating with contiguous generations in a repeatable pattern of specific cellular associations or “stages” (Thomas and Thomas, 2001; França *et al.*, 2005). There is generally only one

stage per seminiferous tubular cross-section in subprimates (França *et al.*, 2005), and each stage transitions into the next at predictable intervals (Senger, 2003). At any given point along a seminiferous tubule, the entire cycle of the seminiferous epithelium occurs over a set time interval closely associated with the spermatogonial turnover rate for that particular mammalian species (Thomas and Thomas, 2001; Haschek *et al.*, 2010). The number and duration of the various stages of the cycle of the seminiferous epithelium vary with species (Senger, 2003), and various classification schemes have been used, based on the morphological characteristics of the spermatid nucleus or the development of the acrosomic system (França *et al.*, 2005). In subprimates, sequential stages are arranged along the length of the seminiferous tubule in consecutive order, forming a "spermatogenic wave" (Senger, 2003; Haschek *et al.*, 2010). The progeny of one spermatogonium A will progress through approximately 4.5 cycles of the seminiferous epithelium before being released into the lumen of the seminiferous tubule and progressing through the rete testis into the excurrent duct system (Thomas and Thomas, 2001). An understanding of the cycle of the seminiferous epithelium is very useful for the evaluation of the effects of xenobiotics on spermatogenesis and for the determination of populations of germ cells most susceptible to a given toxicant.

### Male reproductive physiology

#### *Gonadal steroid synthesis in the testes*

The endocrine events which regulate spermatogenesis and sexual behavior in males are very distinct from those which take place in females (see below). The primary gonadal steroids produced by the testes are androgens (testosterone and DHT (also produced from testosterone in selected non-gonadal tissues)) and estrogens (primarily estradiol in most species), which are now recognized as playing essential roles in male reproductive development and function (O'Donnell *et al.*, 2001; Hess, 2003). Leydig cells in the interstitium synthesize pregnenolone and then progesterone from cholesterol and convert progesterone to testosterone under the influence of LH (Senger, 2003; Genuth, 2004b; Evans and Ganjam, 2011). The site of estrogen synthesis (i.e., aromatase activity) varies with the age and species of animal. In the male fetus, postnatal immature male and, in some species, the adult male, Sertoli cells within the seminiferous tubules play a major role in the aromatase-mediated conversion of testosterone to estradiol under the influence of FSH (O'Donnell *et al.*, 2001; Senger, 2003; Evans and Ganjam, 2011). In many mammals, Leydig cells in the fetal testis and, especially, the postnatal immature testis gradually begin to synthesize estrogens, and, at sexual maturity, a major portion of the estrogens in these species is produced by aromatase activity in the

Leydig cells, under the influence of LH rather than FSH (O'Donnell *et al.*, 2001; Hess, 2003; Evans and Ganjam, 2011). More recently, germ cells have been identified as another potential source of estrogens in the testis, and it is possible that germ cell-derived estrogens play major roles in regulating male reproductive function (Hess, 2003).

#### *Endocrine regulation of spermatogenesis*

While the female hypothalamus has both fully developed tonic and surge centers for GnRH release (especially prior to ovulation), the hypothalamic GnRH surge center in the male is diminished, and the anterior pituitary gland of the male does not experience surges in GnRH stimulation (Senger, 2003; Evans and Ganjam, 2011). This gender-specific alteration in the hypothalamus facilitates the normal endocrine milieu which maintains continuous spermatogenesis and stimulates normal sexual behavior (Figure 19.2). The tonic pulsatile release of GnRH induces the anterior pituitary to produce pulses of LH and FSH several times during the day and facilitates adequate LH-dependent testosterone production and, depending on the species, normal FSH-dependent Sertoli function, both of which are essential for spermatogenesis to occur continuously in the seminiferous tubules (Senger, 2003; Genuth, 2004b; Evans and Ganjam, 2011). In some species, FSH is primarily required for the onset of puberty and the initiation of spermatogenesis, with many of the functions of FSH in the immature male being taken over by testosterone in the sexually mature animal (Haschek *et al.*, 2010).

Testosterone stimulates Sertoli cells to produce several androgen-regulated proteins (including androgen-binding protein), which are required for spermatogenesis (Senger, 2003; Haschek *et al.*, 2010). Interference with this testosterone-mediated effect by antiandrogens (e.g., vinclozolin) which prevent interactions between testosterone and the androgen receptor or by the inhibition of testosterone synthesis by excessive glucocorticoids (e.g., chronic stress, alterations in endogenous glucocorticoid metabolism or the administration of xenobiotics with glucocorticoid-like activities) has the potential to adversely affect Sertoli cell function, and, therefore, spermatogenesis. Estrogens are required for various aspects of the normal development and function of Sertoli cells and germ cells within the seminiferous tubules (O'Donnell *et al.*, 2001; Hess, 2003; Evans and Ganjam, 2011). Xenobiotics which mimic or inhibit the actions of estradiol within the testis can disrupt normal spermatogenesis.

#### *Positive and negative feedback loops involved in male reproduction*

Positive and negative feedback mechanisms help maintain an endocrine environment which is conducive

to normal male reproductive function (Figure 19.2). The Sertoli cell can produce activin and inhibin which respectively increase and decrease the secretion of FSH by gonadotropes and, in some species, GnRH release from the hypothalamus (Haschek *et al.*, 2010). Testosterone, DHT and estradiol all provide negative feedback to the hypothalamus with respect to GnRH release, and testosterone can also directly inhibit LH secretion by gonadotropes (Senger, 2003; Haschek *et al.*, 2010; Evans and Ganjam, 2011). Xenoestrogens and xenoandrogens have the potential to disturb the hypothalamic-pituitary-gonadal axis (O'Donnell *et al.*, 2001). It is currently thought that antiandrogens and a variety of other xenobiotics can interfere with these feedback loops and possibly other endocrine pathways, resulting in Leydig or interstitial cell hyperplasia (Thomas and Thomas, 2001; O'Connor *et al.*, 2002; Evans, 2011b).

#### *Epididymal and accessory sex gland function*

Epididymal development and function are dependent on the proper balance of androgenic and estrogenic stimulation and are required for normal male reproductive function and fertility. The accessory sex glands are considered to be primarily androgen dependent, and the secretions of these glands, as well as those of the epididymis, are important components of seminal fluid. Conversion of testosterone to DHT can generally occur in the epididymis, prostate and seminal vesicles. Hormonally active xenobiotics which alter the normal endocrine events associated with epididymal and accessory gland development and function can have adverse effects on male fertility.

#### *Sexual behavior, erection, emission and ejaculation*

Sexual behavior is mediated by estradiol in postnatal males and females. The conversion of the steadily produced testosterone in the male to estradiol in the brain (plus the effects of estrogens of testicular origin) results in the male being sexually receptive most of the time (Senger, 2003). Adequate libido and sexual receptivity, as well as adequate concentrations of testosterone, are necessary for erection of the penis, which is required for intromission during copulation (Sikka *et al.*, 2005). Olfactory (detection of pheromones), auditory and visual stimuli play roles in facilitating cholinergic and NANC (non-adrenergic/non-cholinergic) parasympathetic neuron-mediated penile erection, which, depending on the species, involves various degrees of nitric oxide-associated vasodilation and vascular engorgement (Senger, 2005; Sikka *et al.*, 2005). During copulation, the events which lead to emission of the secretions of the accessory sex glands and the ejaculation of spermatozoa generally involve tactile stimuli to the glans penis and stimulation by sympathetic neurons (Sikka *et al.*, 2005).

**FIGURE 19.2** The relationship between the tubular and the interstitial compartments of the testicular parenchyma and the endocrine regulation of testicular function in mammalian species is shown. Solid lines indicate positive feedback mechanisms, and dashed lines denote negative feedback pathways. The question mark associated with the production of estradiol by the Sertoli cells and Leydig cells is used to indicate that this hormone, as well as other estrogens, can be produced in the testis by either primarily Sertoli or Leydig cells, depending on the species and stage of development. Although not shown, it should be kept in mind that DHT also provides negative feedback to the hypothalamus and anterior pituitary and germ cells can also aromatize testosterone and produce estradiol. This figure was adapted, with permission, from Garner DL, Hafez ESE (2000) (modifications courtesy of Don Connor and Howard Wilson).

## **Normal female reproductive anatomy and physiology**

### *Reproductive anatomy of the female*

Although there are some distinct morphological differences between species (e.g., simplex uterus in primates, duplex cervixes in rabbits), the female reproductive tract generally consists of paired ovaries and the "tubular genitalia," which include the paired oviducts (uterine tubes) and uterine horns contiguous with a uterine body and cervix, vagina, vestibule and vulva (Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011). The organs involved in female reproductive function are

physiologically and morphologically dynamic and function to produce the oocyte, facilitate its fertilization, provide an environment for embryonic and fetal development, and transport the fetus from the maternal to the external environment. Variations in size, appearance, location and function of the female reproductive organs depend on the endocrine milieu dictated by the effects of sexual maturation, stage of the estrous or menstrual cycle, gestational hormone production of maternal, fetal and/or placental origin, exposure to exogenous HAAs and seasonal influences (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007).

The primary functions of the ovary are oogenesis (production of female gametes (oocytes or ova)) and steroidogenesis (production of estrogens and progesterone). The ovaries of most domestic mammals consist of a peripheral parenchymatous zone (cortex), containing various stages of follicular and luteal gland development and a central vascular zone (medulla), comprised of collagenous connective tissue rich in blood vessels (Senger, 2003; Evans and Ganjam, 2011) (Figure 19.3). The structural and functional unit of the ovary is the follicle. Follicles are classified as primordial, primary (some become atretic), secondary and tertiary (antral) follicles based on their stage of development (Evans *et al.*, 2007; Evans and Ganjam, 2011).

A primary oocyte surrounded by a single, flattened cell layer is a primordial follicle. A basal lamina separates the single layer of what will become granulosa cells from the adjacent stromal tissue which eventually develops into the theca cells (theca interna and theca externa). The granulosa cells homologous to the Sertoli cells in the testis, and the theca interna cells are the female equivalent of the Leydig cells (Senger, 2005). Following the appropriate endocrine stimulation, primordial follicles are recruited to undergo possible further differentiation into estrogen-producing antral follicles and ultimately ovulation, which results in the release of a secondary oocyte (primary oocyte in dogs) and formation of a corpus luteum (CL) which produces progesterone (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011).

### *Female reproductive physiology*

Females are born with a finite pool of primordial follicles (up to hundreds of thousands), and reproductive cyclicity (i.e., estrous or menstrual cycles) provides females with repeated opportunities for the establishment of pregnancy. The majority of mammalian species (subprimates) have estrous cycles, which reflect the physiological changes occurring between successive ovulations and/or periods of sexual receptivity (estrus) (Senger, 2005; Evans and Ganjam, 2011). Humans and non-human primates experience menstrual rather than estrous cycles and do not have defined periods of sexual

receptivity (i.e., estrus). Unlike the estrous cycles in subprimates, the reproductive cycle in menstruating animals is divided into phases (i.e., menses, proliferative and secretory phases), which are defined based on the physiological state of the uterine endometrium, rather than on the predominant ovarian structures (Senger, 2003; Genuth, 2004b; Evans and Ganjam, 2011).

### *The estrous cycle*

The follicular and luteal phases of the estrous cycle describe the predominant ovarian structures and the corresponding gonadal steroid concentrations which result from the follicular secretion of estrogens or the luteal secretion of progesterone, respectively (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007). Both the follicular and luteal phases can generally be further subdivided into two stages each, proestrus and estrus (sexual receptivity) for the follicular phase and metestrus and diestrus (sexual non-receptivity) for the luteal phase (Senger, 2003). Proestrus represents the period of transition from the diestrus dominance of progesterone to the dominance of estrogens during estrus, while metestrus represents the opposite shift in the endocrine milieu (estrogen dominance to progesterone dominance) (Senger, 2003; Evans *et al.*, 2007).

The durations of the various stages of the estrous cycle vary with species and can, depending on the animal in question, either occur throughout the year, multiple times within an ovulatory season that is dependent on photoperiod (long-day or short-day polyestrous animals) or only once a year (Senger, 2003). The domestic bitch does not have a metestrus and, in fact, is actually most receptive to copulation when estradiol is declining and there is a unique, preovulatory surge in progesterone. This endocrine environment predisposes the bitch to cystic endometrial hyperplasia and pyometra following exposure to some xenoestrogens and progestagens. Felids, which are induced (reflex) ovulators, like ferrets, mink, camelids and rabbits, the period of time following an estrus in which copulation has not occurred has been described as post-estrus rather than metestrus because there is no increase in progesterone secretion following the end of sexual receptivity (Senger, 2003). Anestrus is the time period during which reproductive cyclicity ceases and can be seasonal (estradiol and progesterone production are at basal levels) or can be associated with various endocrine milieus related to species of animal, pregnancy, lactation, stress and/or pathological conditions, some of which can be induced by xenobiotics.

### *Follicular development*

The general sequence of endocrine and morphological changes occurring during the estrous cycle involves a variety of positive and negative feedback loops affecting

**FIGURE 19.3** Although there is some interspecies variation with respect to ovarian structure, a schematic representation of a “typical” mammalian ovary is shown to demonstrate the major ovarian structures: (1) medulla; (2) mesovarium; (3) surface epithelium; (4) tunica albuginea, which is poorly developed in the ovary as compared to the testis; (5) primordial follicle; (6) primary follicle; (7) secondary follicle; (8) early tertiary or antral follicle; (9) mature antral follicle; (10) oocyte; (11) ruptured follicle and ovulated secondary oocytes (except for the dog); (12) atretic follicle; (13) CL; (14) atretic CL; (15) corpus albicans. This figure was adapted, with permission, from [Dyce et al. \(2002\)](#) (modifications courtesy of Don Connor and Howard Wilson).

the hypothalamic–pituitary–gonadal axis and leads to the development of antral follicles, the primary source of estrogens, and, eventually, the formation of corpora lutea, which produce progesterone ([Figures 19.3 and 19.4](#)). During the time of year when females are exhibiting reproductive cyclicity, there are cyclic alterations in the pattern of hypothalamic GnRH secretion from the tonic and surge centers, which interact with the anterior pituitary to influence the relative amounts of FSH and LH secreted by anterior pituitary gonadotropes. Over the course of the ovulatory season, many (up to several hundred or more) primordial follicles leave the reserve pool

**FIGURE 19.4** The endocrine regulation of ovarian function and the feedback loops for the hypothalamic–pituitary–gonadal (ovarian) axis in the female are depicted. This figure was adapted, with permission, from [Wilker and Ellington \(2006\)](#) (modifications courtesy of Don Connor and Howard Wilson).

in a cyclic fashion (under the influence of FSH) and enter the active pool of follicles (primary follicles) undergoing growth and differentiation (folliculogenesis) and eventually atresia or ovulation ([Senger, 2003; Evans et al., 2007; Evans and Ganjam, 2011](#)). The oocyte in the developing follicle grows in size, the zona pellucida is formed and the granulosa cells surrounding the oocyte undergo mitosis and further differentiation ([Senger, 2003; Evans and Ganjam, 2011](#)). A primary follicle is transformed into a secondary follicle when there are several layers of granulosa cells. Preantral follicles (primary and secondary follicles) become antral (tertiary) follicles, when fluid from the granulosa cells of secondary follicles coalesces to form an antrum ([Evans et al., 2007; Evans and Ganjam, 2011](#)).

Cyclic increases in FSH concentrations facilitate recruitment antral follicles. Granulosa cells can produce activin which is thought to provide positive feedback to the anterior pituitary, further increasing gonadotropic FSH secretion ([Figure 19.4](#)) ([Senger, 2003; Wilker and Ellington, 2006](#)). Recruited antral follicles, which are gonadotropin sensitive, undergo several waves of follicular development beginning in metestrus and ending in proestrus ([Ginther, 1992; Senger, 2003; Evans et al., 2007](#)). The final wave of one or more dominant follicles, destined for ovulation, rather than atresia, produces the large amounts of estrogens typical of estrus and required for sexual receptivity and the preovulatory estrous surges in GnRH and LH secretion ([Senger, 2003](#)).

#### Ovarian follicular synthesis of estrogens

The production of estrogens (predominantly estradiol) by antral follicles is accomplished by a mechanism termed the “two-cell or two-gonadotropin model,”

which can vary somewhat between species (Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011). Cells from the theca interna and/or granulosa cells (depending on the species) produce progesterone from pregnenolone synthesized from cholesterol and, under the influence of relatively low concentrations of LH, theca interna cells convert this progesterone into androgens and, ultimately, testosterone (Evans *et al.*, 2007; Evans and Ganjam, 2011). In granulosa cells (reportedly theca interna cells in some species), the release of FSH from the anterior pituitary induces aromatase-mediated conversion of testosterone produced in the theca cells into estradiol (Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011). Stimulation of aromatase activity by xenobiotics can have an overall estrogenic effect on exposed animals (increased production of estradiol).

#### *The effects of estrogenic feedback on the hypothalamic–pituitary–gonadal axis*

Increasing concentrations of estrogens associated with estrus alter the hypothalamic GnRH secretory pattern and decrease pituitary secretion of FSH, while greatly increasing the amount of LH produced and released by the anterior pituitary gland (preovulatory LH surge) (Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011). Although inhibin produced by granulosa cells further decreases FSH secretion, dominant follicles surviving to estrus do not undergo atresia because of an enhanced sensitivity to basal FSH levels (Senger, 2003; Wilker and Ellington, 2006). Xenoestrogens have the potential to either imitate or inhibit these estradiol feedback mechanisms in sexually mature females, depending on the amount of estrogenic xenobiotic, the endocrine milieu at the time of the exposure and the relative binding affinity of the xenobiotic for ERs.

#### *Ovulation*

The granulosa cells in the one or more dominant estrous follicles (Graafian follicles) cease to divide shortly prior to ovulation and undergo further differentiation, with increased numbers (up-regulation) of LH receptors which will be responsive to the estrogen-induced preovulatory LH surge (Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011). As LH increases, granulosa cells (theca interna cells in some species) continue to convert pregnenolone to progesterone, but estradiol production decreases, resulting in a slight preovulatory decline in estradiol (Evans *et al.*, 2007; Evans and Ganjam, 2011). The preovulatory LH surge is associated with increased follicular pressure, degeneration of theca cells and weakening of the follicular wall, completion of the first meiotic division within the oocyte (end of meiotic inhibition except in dogs and foxes) and, finally, ovulation of a secondary oocyte arrested in metaphase II (Senger, 2003;

Evans *et al.*, 2007; Evans and Ganjam, 2011). In felids, ferrets, mink, camelids and rabbits, the preovulatory LH surge is induced by copulation (intromission or vaginal stimulation in most induced ovulators; seminal fluid in camelids). Toxicants which interfere with copulation or sexual contact in these species can interfere with the ovulatory process.

#### *Formation and function of a CL*

Following ovulation, a cascade of endocrine changes takes place in the female subprimate which facilitates the transition from sexual receptivity to non-receptivity. Once an ovulation occurs, blood concentrations of follicular estradiol and inhibin return to their basal levels, and granulosa cells continue their growth, differentiation and increased production and release of progesterone (luteinization) under the influence of LH (Evans *et al.*, 2007). The functional ovarian structure which eventually develops from each ovulated follicle is a CL, which is comprised of large and small luteal cells derived from the granulosa and theca interna cells (granulosa cells in horses), respectively (Senger, 2003; Evans *et al.*, 2007). In most species, luteal cells are responsive to LH and produce progesterone until, shortly before the usual end diestrus in non-pregnant animals, the CL undergoes luteolysis mediated by oxytocin-stimulated production of prostaglandins  $F_{2\alpha}$  ( $PGF_{2\alpha}$ ) (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007). While luteolysis is an intraovarian event in primates, oxytocin-stimulated endometrium produces the luteolysin ( $PGF_{2\alpha}$ ) in subprimates (Senger, 2003; Evans and Ganjam, 2011). Xenobiotics, which can cause endometritis or mimic the actions of oxytocin or  $PGF_{2\alpha}$  (e.g., endotoxin or lipopolysaccharide (LPS)) can be associated with premature luteolysis. Conversely, toxicants with the opposite oxytocin/ $PGF_{2\alpha}$ -related effects would be expected to disrupt normal reproductive cyclicity by prolonging the lifespan of the CL and causing a prolonged diestrus or pseudo-pregnancy (e.g., xenoestrogens in swine).

Species of animals can vary in the number of fertile ovulations and, therefore, CLs, which are characteristically associated with each estrous cycle. Monotocous mammalian species usually only ovulate a single secondary oocyte each estrous cycle. The ovaries of litter-bearing (polytocous) mammals generally develop multiple follicles which mature, ovulate and form functional CLs.

#### *Summary of the effects of estrogens and progesterone during the female reproductive cycle*

The endocrine changes which occur during the estrous cycle are reflected in behavior and the size, morphology, position and function of the tubular genitalia. Estrogens have multiple effects on the female

reproductive tract which include: the previously discussed interactions with the hypothalamus and anterior pituitary to alter the patterns GnRH and gonadotropin secretion, which govern follicular development and ovulation; facilitation of sexual receptivity; increased blood flow, genital swelling, leukocytosis, mucosal secretion and myometrial tone; altered tissue electrical conductivity; and initiation of the growth of endometrial and mammary glands (Senger, 2003). Like estrogens, progesterone also has several effects on the reproductive tract of the female, but the effects of progesterone generally oppose those of estrogens, favoring pregnancy maintenance and sexual non-receptivity over ovulation and appropriately timed sexual receptivity associated with estrogenic stimulation (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007). Progesterone is generally associated with negative feedback to the hypothalamus and anterior pituitary gland which limits GnRH and gonadotropin secretion (Senger, 2003; Evans *et al.*, 2007; Evans and Ganjam, 2011). Sexual receptivity and myometrial contractility and tone are diminished in an endocrine environment dominated by progesterone, while mammary and endometrial gland development and secretion are promoted (Senger, 2003). Toxicants which disrupt the communication and coordination between the ovary and the other parts of the reproductive tract (e.g., xenoestrogens, xenoandrogens and anti-estrogens) will alter the appearance and function of the reproductive organs and can interfere with survival of the oocyte, embryo and/or fetus.

## Oocyte/sperm transport, normal capacitation of sperm and fertilization

### *Transport of the ovulated oocyte*

The primary reproductive organs involved in the transport of ovulated secondary oocytes (primary oocytes in the bitch) are the oviducts or uterine tubes. Each oviduct consists of an infundibulum, isthmus and ampulla, which have some distinct differences in structure, as well as function (Evans *et al.*, 2007; Evans and Ganjam, 2011). The ovulated ovum enters the funnel-like opening to the infundibulum and is transported through the isthmus to the ampulla or ampullary-isthmic junction for fertilization. Unlike spermatozoa which can generally survive for several days in the oviduct, secondary oocytes usually, depending on the species, are viable for 12–24 h (Genuth, 2004b). The appropriate endocrine environment is required for adequate oviductal entry and transport of ovulated oocytes to the site of fertilization. Delayed transport of oocytes within the uterine tubes can result in the death of ova before contact can be made with fertile spermatozoa.

### *Transport and capacitation of spermatozoa*

#### *Transport of spermatozoa*

During mammalian copulation, mature sperm stored in the caudae epididymides travel through the vas deferens and penile urethra to be ejaculated into the anterior vagina, cervix or uterine body of the female reproductive tract, depending on the species. Spermatozoa can be lost from the female reproductive tract by retrograde loss and phagocytosis by leukocytes (Senger, 2003). Contractions of the smooth muscle within the tubular genitalia (muscularis), as well as interactions involving components of the seminal fluid and luminal secretions of the female reproductive tract, facilitate the transport of sperm to the oviducts (uterine tubes) where, depending on the species, fertilization takes place in the ampulla or at the junction of the ampulla and the isthmus (ampullary-isthmic junction) (Senger, 2003; Genuth, 2004b). While sperm can be rapidly transported to the ampullary-isthmic junction or ampullae of the oviducts within minutes of natural or artificial semination, the relatively slow, sustained transport of motile sperm from reservoirs of spermatozoa in the cervix and uterotubal junctions is the primary mechanism by which the viable sperm that can participate in fertilization actually enter the oviducts (Senger, 2003). Xenobiotics which interfere with the endocrine milieu required for appropriate muscularis contractility and the cervical and uterine mucosal secretions which facilitate sperm transport (e.g., phytoestrogens) can prevent spermatozoa from getting to the site of fertilization in a timely manner.

#### *Capacitation of spermatozoa*

Spermatozoa can generally survive in the oviducts for several days following insemination. Ejaculated sperm are not competent to either bind to the zona pellucida or to undergo the acrosomal (acrosome) reaction, both of which are required for fertilization of ova by mature spermatozoa. Sperm must be capacitated in order to interact with the ovum. The capacitation process involves calcium influx and biochemical changes to the sperm plasma membrane which result in the “removal” or modification of epididymal and seminal plasma proteins and the exposure of the surface molecules required for spermatozoal binding to the zona pellucida of the ovulated secondary oocyte (Senger, 2003; Genuth, 2004b). Depending on the species and, to some extent, the site of their deposition, spermatozoa become capacitated within the cervix, uterus and/or the oviduct (Senger, 2003).

### *Fertilization*

Fertilization of secondary oocytes by capacitated sperm is a complex process involving a cascade of events

which prevents fertilization of an ovum by more than one sperm (polyspermy) and ends in the fusion of the male and female pronuclei (syngamy) (Senger, 2003; Evans and Ganjam, 2011). In the oviductal ampulla or at the ampullary–isthmic junction, the motility of capacitated sperm becomes hyperactive, facilitating the precise sequence of events which includes the following in their respective order: (1) sperm binding to the zona pellucida of the oocyte involving interactions between species-specific sperm and oocyte proteins; (2) the sperm acrosomal reaction, which results in the release of acrosomal enzymes and exposure of the equatorial segment of the sperm plasma membrane; (3) acrosomal enzyme-associated penetration of zona pellucida by a single spermatozoon; (4) fusion of the plasma membrane of the sperm at its equatorial segment with the plasma membrane of the oocyte; (5) membrane fusion-associated sperm engulfment and the oocyte cortical reaction, which prevents additional oocyte zona binding and membrane fusion (i.e., polyspermy prevention); female pronucleus formation and completion of meiosis; decondensation within the sperm nucleus and male pronucleus formation and, finally, the fusion of male and female pronuclei or syngamy which produces a zygote ready to undergo embryogenesis (Senger, 2003; Genuth, 2004b; Evans and Ganjam, 2011). From the complexity of the fertilization process, it is apparent that toxicants which result in subtle aberrations in sperm and oocyte formation and maturation can have profound effects on gamete function.

## The endocrinology of pregnancy and placentation

### *Gestational hormones*

Pregnancy begins with fertilization of the oocyte within the oviduct, followed by the first cleavage of the zygote, and terminates with parturition. Although the endocrine physiology and duration of mammalian pregnancy are very species specific and are characterized by a great deal of interspecies variation, the overall goals during the entire gestation for all pregnant mammals, their embryo(s) and, eventually, the maternal–fetal–placental unit are the same. A uterine environment conducive to embryonic and fetal development must be facilitated and the pregnancy (pregnancies in multitocous animals) must be maintained for the entire normal gestational length. The primary hormones involved in establishing the proper uterine environment and maintaining pregnancy are progesterone secreted by the maternal ovary and/or the placenta, as well as, in some species, a variety of placental progestagens. In addition, a variety of other endogenous hormones of maternal, fetal

and/or placental origin (depending on the species and gender of the offspring), including androgens, estrogens, prolactin, placental lactogen, equine and human chorionic gonadotropins (eCG and hCG, respectively) and relaxin, also have important gestational functions. Normal embryonic and fetal development require that gestational hormones, especially endogenous androgens and estrogens, be synthesized and secreted in sufficient quantities and at the appropriate time during pregnancy. The proper reproductive development of the female fetus is primarily dependent on exposure to estrogens at specific times during gestation. However, the male fetus must have appropriately timed exposure to normal amounts of both androgens and estrogens for normal development of the reproductive tract and optimal adult reproductive performance (Hess, 2003). Depending on the timing of exposure, EDCs, especially those which function as gonadal steroid receptor agonists and antagonists, can potentially interfere with normal gestational signaling and sexual differentiation.

### *Maternal recognition of pregnancy*

The embryo generally enters the uterus several days after fertilization. One of the first endocrine events which must occur in most mammalian species, other than those for which the timing of luteolysis and duration of pregnancy are very similar to one another (i.e., dogs and cats), is the prevention of luteolysis (i.e., entry into the next estrus or period of sexual receptivity) and the maintenance of luteal phase progesterone concentrations (Senger, 2003; Evans *et al.*, 2007). The mechanism for this embryo–endometrium interaction in subprimates (intraovarian event in primates), also referred to as “maternal recognition of pregnancy,” has been elucidated in several species and involves embryonic production of species-specific interferon- $\tau$  in ovine and bovine species (o-IFN- $\tau$  and b-IFN- $\tau$ , respectively), estradiol secretion by porcine embryos, intrauterine embryonic migration in equids and placental chorionic gonadotropin (hCG) in humans (Senger, 2003; Genuth, 2004b). The timing of “maternal recognition of pregnancy” is species specific and in subprimates generally corresponds to the time period spanning the normal oxytocin-mediated synthesis and release of PGF<sub>2 $\alpha$</sub>  from the endometrium, as well as transport of the luteolysin to the ovary. Xenobiotics which interfere with embryonic and, in the case of humans, placental development or those toxicants which mimic the actions of the luteolysin (e.g., endotoxin) can terminate early pregnancies. Some species of mammals, such as dogs, cats, camelids, goats, swine and rabbits, depend solely on luteal progesterone secretion for the maintenance of pregnancy (Senger, 2003). The placenta takes over progesterone-associated pregnancy maintenance in sheep at approximately 50 days

post-conception and between the 6th and 8th month of gestation in cattle (Senger, 2003). The uterofetoplacental unit of the mare begins to produce a unique assortment of progestagens classified as 5 $\alpha$ -pregnanes, beginning at about day 70 of pregnancy (Ginther, 1992; Evans *et al.*, 2007; Evans, 2011c). A number of toxicants (e.g., ergopeptine alkaloids) have been found to interfere with normal progestagen metabolism in the mare (Evans, 2011c; see Chapter 87 in this book).

### Placentation

Most mammalian species are “eutherian” and, during pregnancy, form a placenta comprised of both fetal and maternal components, which acts as an attachment between the fetal and the maternal systems, functions as a transient endocrine organ and plays essential roles in the exchange of gases, nutrients and metabolic wastes between the maternal and the fetal circulations (Ginther, 1992; Senger, 2003). The yolk sac, chorion, amnion and allantois are the extraembryonic membranes formed by the pre-attachment mammalian embryo (Senger, 2003). While the yolk sac in most mammalian species normally undergoes regression, the allantois and chorion generally fuse to form the allantochorion, and the fluid-filled amnion provides a shock absorbing, aquatic environment to facilitate fetal development and transport (Ginther, 1992; Senger, 2003). The allantochorionic membrane is the fetal contribution to the placenta and the chorionic villi are the structures which interdigitate with the maternal endometrium (Senger, 2003).

### Types of placentas

Mammalian placentation can be classified according to the degree of intimacy between the maternal and the fetal circulations (i.e., the number of tissue layers separating maternal and fetal blood) and by the pattern of distribution of the chorionic villi on the surface of the placenta facing the maternal endometrium (Senger, 2003). Epitheliochorial placentas (placentae) have a total of six layers separating the maternal and fetal circulations and are observed in a variety of species, including equids and swine. Ruminant placentation is described as syndesmochorial because of the transient erosion and regrowth of the maternal epithelium, which results in the intermittent exposure of maternal endothelium (capillaries) to chorionic epithelium (Senger, 2003). Canine and feline placentas are classified as endotheliochorial, and the hemochorial placentation observed in rodents and primates has essentially only chorionic epithelium separating the maternal blood from that of the fetus. The placenta of each species is associated with a typical distribution of the chorionic villi, classified as being either diffuse (e.g., equids and swine), cotyledonary (e.g., ruminants), zonary (e.g., dogs and cats) or discoid

(e.g., rodents and primates). Some species, such as the rabbit, have variations in their placentation over the course of gestation, and what begins as an epitheliochorial placenta has transformed into a hemoendothelial type of placentation by the end of pregnancy (Lehman-McKeeman, 2008).

### Placental function

In multitocous species, each fetus has its own placenta, with the previously described endocrine functions, which “attaches” the fetus to the endometrium and facilitates the exchange of gases, nutrients, metabolic wastes and xenobiotics between the fetal and the maternal circulations. Although the term “implantation” is frequently used to describe the appropriately timed attachment of the placental membranes to the endometrium, only the conceptuses of rodent and primate species undergo true implantation (Senger, 2003). Placental exchange involves the processes of simple (passive) diffusion, facilitated diffusion and active transport, as well as pinocytosis and phagocytosis of some nutrients (Senger, 2003).

The passage of materials across the placenta has been traditionally thought of as primarily a function of the intimacy (i.e., number of tissues layers) between the maternal and the fetal circulations, especially with respect to maternal immunoglobulins which cross hemo- and endotheliochorial placentas but not those types of placentae having more layers. However, since most xenobiotics cross the placenta by simple diffusion, it is currently thought that molecular size and solubility are the most important determinants of the ability of potential teratogens in the maternal circulation to cross the placenta into the fetal circulation (Senger, 2003; Lehman-McKeeman, 2008). Some toxic xenobiotics can be actively transported by mechanisms intended for structurally similar endogenous molecules (Lehman-McKeeman, 2008), and it is thought that transplacental transport of lead can mimic that of calcium (Evans *et al.*, 2003).

### The “placental barrier”

Because the placenta “blocks” the ability of very large molecules to cross from the maternal circulation into the fetal circulation, the term “placental barrier” has been used to describe this protective function of the placenta. Given that a large number of potential toxicants diffuse across the placenta and reach the fetus, the term “barrier” might be somewhat of a misnomer. However, multidrug resistance protein and enzymes involved in biotransformation of xenobiotics have been found in the placenta (Lehman-McKeeman, 2008). The placenta is multifunctional, and regardless of its relative inefficacy as a “barrier” between the maternal and fetal circulations, with respect to at least some xenobiotics, the nutritional and endocrine functions of the placenta are

essential for successful completion of the mammalian pregnancies. Placental toxicity has been discussed in much greater detail in Chapter 20 of this book.

## Normal embryonic and fetal development

### *Blastocyst formation and differentiation of the germ cell layers*

In order for a zygote to develop into a viable offspring, multiple steps involving cellular division, migration, differentiation and organization must take place. Embryonic and fetal survival requires that these various steps take place in a precise order and at set times during the gestation of each species. Within 24h following fertilization, the zygote located in the oviduct begins to divide, within the confines of the zona pellucida, into multiple blastomeres, which ultimately form a ball of cells referred to as the morula (Ginther, 1992; Senger, 2003). A fluid-filled cavity (blastocoele) develops, and the newly formed blastocyst, which is divided into cells forming either the inner cell mass (future embryo proper) or the trophoblast (future chorion), enters the uterus (Senger, 2003). The blastocyst undergoes rapid growth and “hatches” from the zona pellucida. The subsequent cellular division and differentiation results in the formation of the three germ layers (i.e., endoderm, mesoderm and ectoderm), which are destined to develop into the embryonic tissues forming the various organs and body systems, as well as the extraembryonic membranes involved in placental formation and attachment (Ginther, 1992; Senger, 2003). Germ layer differentiation leads to organogenesis and the transformation of an embryo into the fetus which continues to grow and develop for the remainder of pregnancy. With respect to reproductive toxicity in non-rodent mammals, the organogenic and other developmental processes occurring during the first trimester of pregnancy are especially susceptible to the teratogenic effects of xenobiotics. The abnormalities induced by a teratogen are dependent on the specific developmental processes or signaling pathways targeted by that toxicant and the timing of the exposure.

### *Sex determination and sexual differentiation of reproductive function*

#### *Genotypic sex and development of the primitive sex cords*

The genotypic sex of a mammalian conceptus is determined at fertilization by the sex chromosome (X or Y) contributed by the sperm, which, in combination with the X chromosome in the ovum, denotes either a genotypically female (XX) or a male (XY) zygote. During early gestation in most species, the primordial germ cells arise from the epithelium of the embryonic yolk sac

and migrate through the developing mesentery to the gonadal (genital) ridge (testicular or ovarian anlage) in its position contiguous with the mesonephros (Senger, 2003; Evans *et al.*, 2007). Germ cells and stimulated somatic cells proliferate and organize into primitive sex cords within undifferentiated (bipotential) gonads, which have the potential to develop into either ovaries or testes (Senger, 2003; Basrur, 2006).

#### *Gonadal sex determination and phenotypic sexual differentiation*

Development of a phenotypically male or female mammalian fetus occurs during the first trimester of pregnancy in most species and consists of the determination of gonadal sex followed by the further development and differentiation of either the mesonephric or the paramesonephric ducts and regression of the other duct system. The selection of the mesonephric or paramesonephric ducts for retention and further differentiation results in the formation of genitalia (phenotypic sex) appropriate for either the male or female gonads, respectively (Genuth, 2004b). Gonadal sex determination and phenotypic sexual differentiation are dependent on complex and carefully timed signaling events and are extremely susceptible to disruption by xenobiotics. Toxicants which alter epigenetic programming or mimic or inhibit endogenous hormones can have potentially deleterious effects on sexual development (Basrur, 2006). Xenobiotic-induced abnormalities in phenotypic sexual differentiation can arise from defects in testicular formation, defects in androgen production and defects in androgenic action (Basrur, 2006; Hughes *et al.*, 2006). While some toxicant-induced abnormalities in sexual differentiation can be very obvious (e.g., hermaphroditism (presence of ovotestes), pseudohermaphroditism (differences in gonadal and phenotypic sex), hypospadias (feminized external genitalia; failure of urethral fold fusion) and cryptorchidism (failure of testicular descent)), other more subtle effects can be related to functional rather than structural abnormalities. In order to identify the steps in gonadal sex determination and phenotypic sexual differentiation most likely to be targeted by the effects of EDCs and other reproductive toxicants, it is important to understand how these processes are initiated within the fetus and how they impact subsequent fetal development.

For the last several decades, the model for gonadal sex determination and phenotypic sexual differentiation has been based on the premise that a “testis determining factor” (TDF) on the Y chromosome dictates that a gonad differentiates into a testis and initiates the cascade of endocrine changes (Figure 19.5) which results in a phenotypically male fetus (developed mesonephric duct system; regressed paramesonephric ducts) (Senger, 2003; Genuth, 2004b; Basrur, 2006; Evans and Ganjam, 2011). Without the

determination that the gonads will develop into testes, the “default” or “constitutive” pathway is followed and ovarian gonads are formed in association with a developed paramesonephric duct system and regressed mesonephric ducts (Senger, 2003; Genuth, 2004b; Basrur, 2006). While this model is useful to explain rather complex developmental processes, it should be kept in mind that other toxicant-susceptible mechanisms might also play a role in gonadal sex determination and sexual differentiation. It is apparent that very precise, sex-specific patterns of germ line epigenetic programming and interactions with somatic cells take place during the early stages of sexual differentiation (Anway and Skinner, 2006). Recent data have suggested that these signaling pathways are susceptible to epigenetic modifications induced by some antiandrogens (Anway *et al.*, 2005; Anway and Skinner, 2006). It has also been suggested that gonadal sex determination involves other genes on both sex and autosomal chromosomes that might be targeted by reproductive toxicants (Genuth, 2004b; Basrur, 2006).

#### *Development of the male phenotype*

Once previously undifferentiated gonads commit to testes development (TDF present), a coordinated series of endocrine-induced morphological changes take place, resulting in both a genotypically and a phenotypically male fetus (Figure 19.5a). The sequence of signaling and developmental changes, which result in male sexual differentiation, include the following: (1) Sertoli cell development and secretion of anti-Müllerian hormone (AMH) or Müllerian inhibiting substance (MIS); (2) AMH-induced regression of the paramesonephric (Müllerian) ducts and differentiation of Leydig cells capable of producing testosterone; (3) testosterone-facilitated development of the mesonephric or Wolffian ducts; (4) differentiation of the mesonephric ducts into the rete testes, efferent ductules, epididymides and ducti deferens; (5) development of primordial accessory sex glands and the formation of external genitalia from primordia and, finally, in most species (some exceptions in wildlife species); (6) testicular descent of the intra-abdominal testes into their extra-abdominal position in the scrotum, prior to or very shortly after birth (some species) (Senger, 2003; Genuth, 2004b; Basrur, 2006; Edwards *et al.*, 2006).

#### *Development of the female phenotype*

If the previously undifferentiated gonads do not commit to testes development (TDF absent), ovaries are formed and a cascade of morphological changes occurs in the absence of AMH and testosterone stimulation, resulting in a genotypically and phenotypically female fetus (Figure 19.5b). This sequence of “default” or “constitutive” morphological and endocrine alterations results in the following sequence of developmental events: (1)

regression of mesonephric (Wolffian ducts); (2) differentiation of the paramesonephric (Müllerian) ducts into the oviducts, uterine horns, uterine body, cervix and anterior vagina; (3) remodeling of the ovary into its typical parenchymal and cortical structure; (4) cortical development of primordial follicles, with primary oocytes arrested in meiosis and surrounded by future granulosa and theca interna cells; and (5) development of the caudal vagina and vulva from the urogenital sinus (external genitalia primordia) (Senger, 2003; Genuth, 2004b; Basrur, 2006; Edwards *et al.*, 2006; Evans *et al.*, 2007).

#### *Sexual differentiation of the brain*

Sex-specific endocrine patterns and the resulting gender appropriate sexual behaviors in animals are necessary for fertile copulations to occur and require that the brain also undergo prenatal (postnatal in some species) sexual differentiation. Although large amounts of estradiol defeminize the brain, alpha-fetoprotein prevents most of the endogenous estrogens in the female fetus from crossing the blood–brain barrier (Senger, 2003). The brain remains inherently female under the influence of minimal amounts of estradiol, and both the GnRH tonic and surge centers are maintained within the hypothalamus of the female fetus in this low-estradiol environment (Ford and D’Occhio, 1989; Senger, 2003). Testosterone produced by the fetal testes crosses the blood–brain barrier and is converted to estradiol within the brain, and, as a result of this estradiol synthesis, the hypothalamic GnRH surge center in the male fetus is minimized (Senger, 2003).

While the differentiation of male sexual behavior in large domestic animals generally involves prenatal defeminization, especially in species having longer gestations, it should be noted that postnatal defeminization of the brain is occurs in male swine and rodents (Ford and D’Occhio, 1989). There is also evidence to suggest that the males of some species with prenatal defeminization of the brain might also require postnatal exposure to androgens for maximum masculinization of the brain (Senger, 2003). Depending on the timing of exposure, xenoestrogens and exogenously administered testosterone and, possibly, some xenoandrogens, which cross the placenta and the blood–brain barrier have the potential to have profound effects on sexual differentiation of the brain and future reproductive function.

## **Parturition and lactation**

### *Physiology of parturition*

Parturition constitutes transport of the fetus and its associated membranes from the maternal to the external environment, and represents transition of the fetus to a

**FIGURE 19.5** The initial stages in the development of the testis and the formation of the excurrent duct system are shown in (A). The initial formation of the tunica albuginea isolates the epithelial cords from the surface epithelium, and the epithelial cords, rete testis and mesonephric tubules (also referred to as the mesonephric ductules or mesonephric duct system) subsequently interconnect. The epithelial cords (sex cords) will eventually become the seminiferous tubules, and the mesonephric ductules will be incorporated into the formation of the excurrent duct system. (1) Celomic epithelium; (2) tunica albuginea; (3) epithelial cords (future seminiferous tubules); (4) rete testis; (5) mesonephric tubules (later efferent ductules); (6) mesonephric duct (future epididymis (proximal portion contiguous with mesonephric tubules and ductus deferens (distal portion))); (7) paramesonephric duct; (8) cranial remnant of mesonephric duct system (aberrant ductules); (8') remnant of mesonephric duct (appendix of epididymis); and (9) caudal remnant of mesonephric duct (paradidymis). The initial stages in the development of the ovary and the formation of paramesonephric ducts are shown in (B). The epithelial cords (sex cords) penetrate and then regress within the developing ovary, eventually fragmenting and organizing into cell clusters which consist of a single oocyte surrounded by a layer of granulosa cells (primordial follicles). The paramesonephric ducts undergo further development and differentiation, and the mesonephric duct system begins to regress: (1) celomic epithelium; (2) epithelial cords which initially penetrate then regress and fragment; (3) early formation of future cortical region; (4) primordial follicles; (5) regressing mesonephric tubules; (6) mesonephric duct which will eventually regress; and (7) paramesonephric duct which will undergo further development and differentiation into the major female tubular genitalia. This figure was adapted, with permission, from [Dyce \*et al.\* \(2002\)](#) (modifications courtesy of Don Connor and Howard Wilson).

neonate. Maturation of the fetal hypothalamic–pituitary–adrenal axis plays an important role in the cascade of neural and endocrine events which lead to parturition in most mammals ([Senger, 2003](#); [Evans \*et al.\*, 2007](#)). As most clearly demonstrated in ruminants, fetal CRF stimulates the release of ACTH from the fetal pituitary, and ACTH, in turn, stimulates fetal secretion of cortisol by the adrenal glands ([Senger, 2003](#)). Elevations in fetal cortisol (fetal LH may be involved as well) activate placental

steroidogenic enzyme systems, resulting in decreased progestagens and elevated estrogens prior to parturition ([Ginther, 1992](#); [Evans \*et al.\*, 2007](#)). The resulting increase in the estrogen:progestagen ratio facilitates several important processes (e.g., cervical softening, up-regulation of myometrial oxytocin receptors, uterine synthesis of PGF<sub>2α</sub> and increased blood flow to the gravid uterus and placenta) which prepare the uterus for parturition ([Evans \*et al.\*, 2007](#)). Teratogen-induced congenital defects

in the fetal pituitary gland can result in prolonged gestation (e.g., *Veratrum californicum*), and any xenobiotic exposure causing maternal and/or fetal stress can be associated with abortion or premature parturition (e.g., nitrates and pine needle abortion).

Normal parturition approaches as neural signals caused by fetal movements and myometrial contractions, along with elevated basal levels of oxytocin and increased secretion of  $\text{PGF}_{2\alpha}$ , bring about the first stage of labor. A rapid increase in oxytocin and  $\text{PGF}_{2\alpha}$  secretion leads to rupture of the allantochorionic membrane and the commencement of the second stage of labor. Strong myometrial contractions result in the delivery of offspring, as well as the expulsion of the fetal membranes during the third stage of labor (Senger, 2003; Evans *et al.*, 2007).

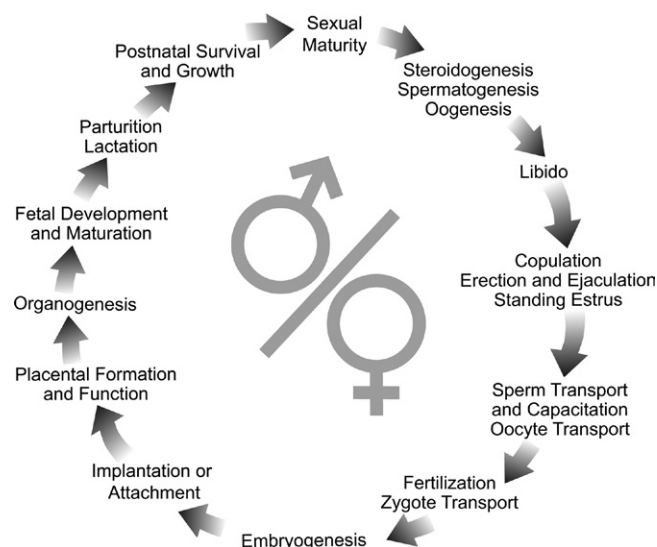

### Physiology of lactation

#### Lactogenesis

Appropriately timed lactogenesis is critical for survival of mammalian offspring. Lactogenesis is a two-stage process involving: (1) the enzymatic and cytological differentiation of the alveolar cells within the mammary gland and (2) the copious secretion of milk, which is distinct from the colostral sequestration of antibodies (Tucker, 1994). Growth hormone, aldosterone, prostaglandins, insulin, estrogens, progestagens and prolactin are required for the first stage of lactogenesis, which generally occurs during the last trimester of pregnancy (McCue, 1993; Tucker, 1994). Large increases in pulsatile prolactin secretion by lactotrobes in the anterior pituitary are necessary for the initiation of the second stage of lactogenesis, which generally occurs in close temporal association with the endocrine milieu of parturition (Evans, 1996). In many species, circulating concentrations of prolactin are elevated above basal levels for a month or two after parturition (McCue, 1993). In some species of animals, a placental lactogen performs many of the same endocrine functions as prolactin.

#### Control of prolactin secretion

Lactotropic prolactin secretion is tonically inhibited by dopamine secreted by hypothalamic neurons belonging to either the tuberoinfundibular or tuberohypophysial dopaminergic systems (TIDA and THDA, respectively) (Neill and Nagy, 1994; Evans *et al.*, 2007; Evans and Ganjam, 2011). Vasoactive intestinal peptide (VIP) and TRH are thought to act as prolactin releasing factors and can interfere with the dopamine-associated tonic inhibition of prolactin release (Evans, 1996). Oxytocin, in conjunction with the suckling reflex, will increase pituitary lactotropic production and secretion of prolactin (Neill and Nagy, 1994). In species strictly dependent on

**FIGURE 19.6** The multiple steps involved in reproductive development and function in both males and females are shown schematically to illustrate the complexity of reproduction in mammalian species and to demonstrate the various stages in the reproductive process which can be targeted for toxic insult. With respect to embryonic, fetal and placental development, it should be understood that these events are species dependent and interrelated, with many of them taking place concurrently. This figure was adapted, with permission, from Ellington and Wilker (2006) (modifications and artwork courtesy of Don Connor and Howard Wilson).

prolactin for lactogenesis (e.g., equids and swine), toxicants which mimic dopamine and tonically inhibit prolactin secretion (e.g., ergopeptine alkaloids) pose a risk to fetal survival (Evans, 2011c; see Chapter 87 in this book).

## THE MECHANISMS AND EFFECTS OF REPRODUCTIVE TOXICANTS

### The effects of EDCs on wildlife species, humans and domestic animals

It should be evident from the previous discussion that maximum reproductive efficiency, including normal embryonic and fetal development, is dependent on the structural and functional integrity of multiple organs and tissues, as well as various signaling pathways (Figure 19.6). Within the broad definition for “endocrine disruption” used in this chapter, without any restrictions as to whether the xenobiotics involved are synthetic or naturally occurring or by which specific mechanism they exert their endocrine effects, no doubt should remain in even the harshest skeptic’s mind that “endocrine disruption” is a real phenomenon. The current debate should not focus on “whether” endocrine disruption occurs, but, rather, “when” it occurs and under what

circumstances. There is increasing concern within the scientific and regulatory communities regarding the effects of prenatal and early postnatal exposures to EDCs on wildlife species and humans (Evans, 2011b). Domestic animals have been known to be susceptible to the effects of several naturally occurring reproductive toxicants in clinical settings, and it is possible that low-level environmental exposures to EDCs can also hinder reproductive function in these species (Evans, 2011a).

#### *Endocrine disruption in wildlife species*

There have been many, well-documented instances of reproductive abnormalities in species of wildlife living in environments contaminated by industrial and/or agricultural chemicals (McLachlan, 2001; Hess and Iguchi, 2002; Jobling and Tyler, 2006; McLachlan *et al.*, 2006). The deleterious reproductive effects of DDT on birds reported in Rachel Carson's *Silent Spring* have been shown to be the result of eggshell thinning related to abnormalities in prostaglandin synthesis induced by the *p,p*-DDE metabolite of DDT (Lundholm, 1997; Guillette, 2006). Wildlife populations are very likely sentinels for endocrine disruption because of the contamination of the aquatic habitats in which many of them live and the likelihood that predatory animals will have relatively high exposures to chemicals which bioaccumulate within the environment (Hess and Iguchi, 2002). Lessons learned from instances of endocrine disruption in wildlife species can be applied to EDC exposures involving humans and domestic animals (Evans, 2011b).

#### *"Androgenic" and "estrogenic" effects of EDCs on wildlife species*

Prenatal and postnatal exposures to androgenic and estrogenic environmental contaminants, as well as chemicals classified as having the opposite phenotypic effects, have been associated with various reproductive abnormalities in wildlife. Effluents from pulp and paper mills, as well as runoff from cattle feedlots where the synthetic androgen trenbolone was used for growth promotion, have been shown to be androgenic and capable of masculinizing female fish (Orlando *et al.*, 2004; Gray *et al.*, 2006). "Androgenization" or a state of indeterminate sexual development encompassing both feminization and demasculinization in males has been observed in populations of fish, amphibians, reptiles, birds and mammals and is thought to be similar to the testicular dysgenesis syndrome described in humans (Edwards *et al.*, 2006). Adult and immature amphibians exposed to the herbicide atrazine, which has been associated with increased aromatase activity in a number of species, have been reported to exhibit various manifestations of feminization (Hayes *et al.*, 2006). Hatchling, juvenile and adult male alligators (*Alligator mississippiensis*), originating

from a Florida lake previously contaminated with DDT and other persistent, bioaccumulated pesticides, as well as ethylene dibromide and DBCP, have demonstrated varying patterns of androgenization, including phallic malformations, which are thought to result from ovo exposure of maternal origin, as well as post-embryonic modifications and/or continuing environmental exposures to EDCs (Milnes *et al.*, 2006).

#### *Endocrine disruption in humans*

Based, in part, on the observations of endocrine disruption in wildlife and ongoing concerns about reproductive dysgenesis, as well as the effects of embryonic and/or fetal exposure to diethylstilbestrol (DES), the emphasis with respect to endocrine disruption in humans and one of the bases for the "Theory of Hormone Disrupting Chemicals" (THDC) or the "Environmental Endocrine Hypothesis" (Krimsky, 2000, 2001) has been the enhanced effects of prenatal, as compared to postnatal, exposures to suspected endocrine disruptors. The embryo and fetus, without a developed blood-brain barrier and with only rudimentary DNA repair mechanisms and hepatic detoxifying and metabolizing capabilities, are especially susceptible, as compared to adults, to the adverse effects of low-level exposures to xenobiotics (Newbold *et al.*, 2006). In addition, previous discussions in this chapter and other textbooks have described the important organizational events taking place during gonadal and phenotypic sexual differentiation, which are potentially very sensitive to alterations in the normal endocrine milieu (Evans, 2011b).

Although still controversial, there is a growing body of evidence to support the observation that sperm counts in men within some industrialized regions of the world have been decreasing over the last several decades (Swan *et al.*, 2000; Skakkebaek *et al.*, 2006; Jørgensen *et al.*, 2006a). In conjunction with these alterations in sperm numbers within ejaculates, there appears to have been a concurrent increase in developmental abnormalities within the male reproductive tract consistent with TDS (Skakkebaek *et al.*, 2001). Similar to what has been observed in xenobiotic-exposed wildlife, reproductive dysgenesis in human males (i.e., TDS) is associated with a suite of clinical abnormalities which include reduced semen quality, cryptorchidism, hypospadias, decreased anogenital distance and testicular cancer (Skakkebaek *et al.*, 2001; Edwards *et al.*, 2006). Failure of Sertoli cell proliferation and functional maturation within the seminiferous tubules has been one mechanism proposed for the pathogenesis of TDS (Sharpe *et al.*, 2003). The findings of a recently completely epidemiological study have suggested a relationship between decreased anogenital distance and prenatal phthalate exposure in male infants (Swan *et al.*, 2005), and a possible rodent model for

human TDS has been developed using prenatal exposure to dibutyl phthalate [di (*n*-butyl) phthalate] (Fisher *et al.*, 2003; Mahood *et al.*, 2005, 2006).

In addition to phthalates, which are used as plasticizers, a number of other widely used agricultural and industrial chemicals have been associated with adverse reproductive effects in humans and/or rodent models. In epidemiological studies a correlation has been shown between reduced semen quality in men within certain regions of the United States and the metabolites of several economically important herbicides (Swan *et al.*, 2003a, b). Metabolites of the commercially available fungicide vinclozolin have been demonstrated to interfere with interactions between androgens and their nuclear receptor, resulting in antiandrogenic effects on exposed rodents (Wong *et al.*, 1995; Monosson *et al.*, 1999; O'Connor *et al.*, 2002; Kubota *et al.*, 2003; Gray *et al.*, 2006). It has been reported that, at concentrations well below those routinely found in humans, bisphenol A, which is widely used in the plastics industry and other manufacturing processes, can initiate nongenomic estrogenic responses with plasma membrane receptors and interact with the nuclear estrogen receptor as a SERM (Welshons *et al.*, 2006). It has also recently been reported that, as might be expected, more bisphenol A is absorbed if included in the diet similar to what would be observed in actual environmental exposures, as opposed to administered as an oral bolus, which is normally what occurs in an experimental setting (Sieli *et al.*, 2011). Concerns have also been raised about the antiandrogenic activity of pyrethroid insecticides (Zhang *et al.*, 2008), which are commonly used without the awareness that these compounds have the potential to affect reproductive function at levels of exposures less than those associated with neurotoxicity. With the increased societal awareness of the possible effects of hormonally active xenobiotics on human reproduction, further research is required to make educated decisions, based on "good science," with respect to label instructions and precautions for continued use and/or regulation of economically important chemicals associated with the potential for reproductive abnormalities in humans and/or documented impairment of reproductive function in laboratory animals.

### **The effects of reproductive toxicants on domestic animals**

#### *Abortion, teratogenesis and impaired fertility in domestic animals*

Animal-based agriculture is dependent on the efficient production of viable and reproductively functional offspring. Toxicant-induced abortions, congenital defects and male or female infertility can have devastating effects on livestock production. Cattle are commonly at increased risk, especially under drought conditions, for

adult mortality and abortions in pregnant cows related to the consumption of nitrate-accumulating forages (e.g., *Sorghum* spp., oat hay (*Avena sativa*), cornstalks (*Zea mays*), and many others), which cause nitrite-induced fetal methemoglobinemia, hypoxia and, consequently, fetal stress and, potentially, even death (Casteel and Evans, 2004). Multiple congenital contractures (MCC) ("crooked calf disease") associated with the ingestion of lupines (*Lupinus* spp.) have resulted in the loss of large numbers of calves in the western United States (Panter, 2002), and multiple species of livestock exposed to swainsonine-containing plants (e.g., species of *Astragalus* and *Oxytropis* in North America species of *Swainsona* in Australia) have experienced congenital defects, abortions and/or ovarian and testicular abnormalities (Cheeke, 1998). Cleft palate, cyclops lambs, prolonged gestation and various tracheal and limb deformities have resulted from different periods of exposure of pregnant ewes to *Veratrum californicum* (false hellebore) (Burrows and Tyrl, 2001). Ergot alkaloids produced by the tall fescue endophyte *Neotyphodium coenophialum* are responsible for suboptimal reproductive performance in large numbers of cattle and horses, with late-gestational mares being particularly susceptible to endophyte-related prolonged gestation and agalactia (Evans *et al.*, 2004; see Chapters 87 and 89 of this book).

#### *Endocrine disruption in domestic animals*

With respect to the adverse reproductive effects of endocrine disruption on domestic animals, there have been many instances of impaired reproductive function involving naturally occurring EDCs of plant and fungal origin. However, there is still much to be learned about the potential adverse effects of pre- as well as postnatal environmental exposures to EDCs in these species where selection of breeding animals is often based on reproductive soundness. Postnatal exposures to phytoestrogens in some leguminous plants, including soybeans, have resulted in reproductive abnormalities and subfertility in multiple species (Cheeke, 1998; Ford *et al.*, 2006). The adverse effects of postnatal exposures to the estrogenic mycotoxin zearalenone on swine fertility have also been well documented (Cheeke, 1998). Many of the reproductive effects of the common forage-related disease syndrome referred to as "fescue toxicosis" clearly involve the endocrine disruptive effects of ergot alkaloids on prolactin secretion. In experimental studies, female swine appear to be more sensitive than rodents to the effects of the synthetic herbicide atrazine on the hypothalamic-pituitary-gonadal axis (Gojmerac *et al.*, 2004), and it is possible that companion and agricultural animals are also more susceptible than laboratory species to other EDCs. As many hormonally active xenobiotics also have important agricultural and industrial uses, it is important to continue research which attempts

to accurately predict the effects of environmental exposures to EDCs, as well as other reproductive toxicants, on domestic animals.

## Toxicants affecting the male reproductive function

There have been relatively few documented reports regarding the adverse effects of reproductive toxicants on male fertility in the major animal species of veterinary interest. Realistically the lack of examples is more likely a reflection of the limited number of controlled studies performed using non-rodent mammalian species and/or the number of toxicant-associated reproductive abnormalities which remain undiagnosed, rather than an accurate indication of the scope of the problem (Schrader, 2002). A large number of chemicals are currently thought to have the potential for causing abnormalities in male reproductive function in domestic animals. Based on extrapolations from effects observed in a various mammalian species and the limited scientific and anecdotal reports, a partial listing of these compounds is presented in Table 19.1 (Ellington and Wilker, 2006). In the following section a few selected male reproductive toxicants and their proposed mechanisms of action will be described in order to familiarize the reader with the various different ways that male fertility can be affected by reproductive toxicants.

### *Selected male reproductive toxicants and mechanisms of action*

#### *Cell-specific reproductive toxicants*

Some reproductive toxicants adversely affect specific cells within the testes. Ethane dimethane sulfonate is specifically cytotoxic to the Leydig cells, and excessive exposure to this compound results in complete loss of this population of cells within the interstitium, and, consequently, the ability of the testes to synthesize testosterone and, in some species, estrogens (Haschek *et al.*, 2010). Tri-*o*-cresyl phosphate (TOCP) is an industrial chemical used in lacquers and varnishes, which inhibits LH-induced steroidogenesis in the Leydig cells and, after Leydig cell-mediated conversion to its active metabolite, morphological abnormalities in Sertoli cells (Thomas and Thomas, 2001; Haschek *et al.*, 2010).

Sertoli cells are specifically targeted by several toxicants, including diethylhexyl phthalate (DEHP), 1,3-dinitrobenzene (DNB) and 2,5-hexanedione (metabolite of *n*-hexane) (Haschek *et al.*, 2010) and the effects of these xenobiotics are age and species specific (Thomas and Thomas, 2001). With respect to DNB, the parent compound is converted to its toxic metabolites,

nitrosonitrobenzene and nitroaniline, within the target Sertoli cells, and, similar to other Sertoli cell-specific toxicants, germ cell death and exfoliation occur secondary to toxic insult to the Sertoli cells (Haschek *et al.*, 2010). Sertoli cell microtubules appear to be the intracellular targets of 2,5-hexanedione (Thomas and Thomas, 2001; Haschek *et al.*, 2010). The fungicide dibromochloropropane (DBCP) appears to affect the Sertoli cell (Thomas and Thomas, 2001), but its metabolites epichlorhydrin and  $\alpha$ -chlorhydrin induce capillary permeability and vascular damage within the epididymis (Haschek *et al.*, 2010).

There are a number of reproductive toxicants which target-specific populations of germ cells. Spermatogonia, spermatocytes, round spermatids and elongate spermatids are specifically targeted by busulfan, 2-methoxyethanol, ethylmethane sulfonate and dibromacetic acid, respectively (Haschek *et al.*, 2010). Ionizing radiation and a variety of chemotherapeutic agents, including cyclophosphamide, nitrogen mustard, vincristine and vinblastine, generally target rapidly dividing mitotic or meiotic germ cells in the testes, and TCDD appears to adversely affect several populations of spermatozoal precursors (Thomas and Thomas, 2001). The compound 7,12-dimethylbenz[*a*]anthracene (DMBA) is toxic to spermatogonia but must undergo a stepwise biotransformation in the Leydig cell and, subsequently, the Sertoli cell to produce the ultimately toxic metabolite (Haschek *et al.*, 2010).

#### *Heavy metals*

Lead and cadmium are ubiquitous heavy metals and have both been associated with testicular toxicity and impaired fertility in a number of species. Excessive cobalt can potentially interfere with normal spermatogenesis, and severe cobalt intoxications have actually resulted in generalized hypoxia related to increased blood viscosity which affects the testes (Thomas, 1995). Chromium and vanadium have also been associated with adverse reproductive effects (Thomas and Thomas, 2001), and cis-platinum exposure has been associated with the death of spermatocytes and spermatids, as well as disruption of Sertoli cell tight junctions (Thomas, 1995). Although testicular toxicity is generally not observed with excessive parenteral exposure to zinc (other than possibly secondary to hemolytic anemia-related hypoxia) (Thomas, 1995), intratesticular injections with zinc gluconate have been successfully used for chemical castration in several species.

Divalent lead is known to interact with physiological processes involving calcium and generally has an affinity for sulfhydryl groups. Lead is reported to be directly toxic to germ cells and Leydig cells and can suppress anterior pituitary secretion of LH and FSH (Thomas and Thomas, 2001). Lead also appears to be able to adversely

TABLE 19.1 Xenobiotics/environmental and physiological factors that affect male fertility

Xenobiotic	Observed effect(s) on male
<i>Antimicrobials</i>	
Metronidazole	High doses: ↓ sperm number; ↑ abnormal morphology
Nitrofurantoin	High doses: ↓ sperm number
Tetracycline	Very high doses: ↓ sperm number; ↓ sperm capacitation; testis atrophy
Trimethoprim	1-month course: ↓ sperm number by 7–88%
<i>Antifungals</i>	
Ketoconazole	Decreased testosterone and libido; ↓ sperm number and motility
Miconazole	Interferes with testosterone in male fetus
<i>Immunosuppressants</i>	
Cyclophosphamide	Decreased sperm number; birth defects in offspring
<i>Hormones</i>	
Testosterone	Decreased sperm number; testicular degeneration
Anabolic steroids	Decreased sperm number, motility and morphology
Trenbolone	Increased sperm abnormalities
Estrogens	Decreased sperm number; behavioral feminization
Phytoestrogens	Bioaccumulation in cats on soy diets can cause poor fertility
Zearanol	Decreased spermatogenesis
<i>Antivirals</i>	
Acyclovir	Dose- and age-dependent testicular degeneration
Ganciclovir	Decreased sperm number and quality
<i>Carbonic anhydrase inhibitors</i>	
Acetazolamide	Decreased libido and impotence
<i>Psychoactive drugs</i>	
Buspirone	Decreased libido and impotence
Benzodiazepine tranquilizers	Impotence and possible ejaculatory dysfunction
Phenothiazine tranquilizers	Priapism and impotence
Tricyclic antidepressants	Decreased libido and erectile dysfunction
<i>Antihistamines</i>	
Chlorpheniramine	<i>In vitro</i> experiments: ↓ sperm motility
<i>Antineoplastics</i>	
Adrimycin	Dose- and age-dependent testicular toxicity
Cisplatin	Decreased sperm number; ↓ growth in offspring; pregnancy loss
Vincristine	Decreased sperm number; possible reversibility
<i>Antimetabolite</i>	
Cytarabine	Decreased sperm number
<i>Gastrointestinal tract drugs</i>	
Cimetidine	Decreased sperm number
Metaclopramide	Impotence
<i>Non-steroidal antiinflammatories</i>	
Naproxen	Decreased seminal prostaglandins; ↓ sperm motility
Phenylbutazone	Inhibition of sperm acrosome reaction; unknown effect on fertility
Sulfasalazine	Decreased sperm number and motility
<i>Glucocorticoids</i>	
Prednisone	Decreased sperm number and motility; ↓ testosterone
<i>Herbicides</i>	
2,4-D (dichlorophenoxyacetic acid)	Abnormal sperm quality; testicular degeneration; ↓ fertility
Diquat and paraquat	Altered sexual differentiation in the male
<i>Solvents</i>	
Nitrobenzene	Decreased sperm number and motility; testicular degeneration
Naphtha	Decreased fertility
<i>Phthalic acid esters</i>	
Diethylhexaphthalate (DEHP)	Testicular atrophy
<i>Gasoline additives</i>	
Ethylene dibromide	Testicular degeneration and poor sperm quality
<i>Insecticides</i>	
Carbamates	Decreased sperm quality
Chlorinated hydrocarbons	Testicular degeneration and atrophy
Methoxychlor	Testicular degeneration associated with estrogenic activity
Kepone	Decreased sperm number
Lindane	High doses: testicular toxicant
	In utero exposure: ↓ sperm number and ↓ testosterone in offspring

(Continued)

TABLE 19.1 (Continued)

Xenobiotic	Observed effect(s) on male
Organophosphates	No information
Pyrethrins	<i>In vitro</i> : 40–60% ↓ in testosterone binding to androgen receptor
<i>Fungicides/nematocides</i>	
DBCP (dibromochloropropane)	Decreased sperm number; testicular toxicant
<i>Fungicide</i>	
Vinclozolin	Antandrogen: disruption of male phenotypic sexual differentiation
<i>Heavy metals</i>	
Cadmium	High doses: ischemic necrosis of the testis
Chromium	Decreased testosterone; ↓ sperm number
Lead	Decreased testosterone; ↓ sperm number; ↓ fertilization rates
Mercury	Decreased sperm quality
<i>Miscellaneous xenobiotics</i>	
Dioxin	Decreased libido; abnormal sperm morphology; ↓ response to GnRH
DBP (dibutyl phthalate)	Altered sexual differentiation
PCBs	Decreased sperm number; altered hypothalamic–pituitary–adrenal axis
Gossypol	Decreased sperm number
Ethylene glycol	Decreased sperm number and motility
<i>Environmental factors</i>	<i>Observed effect(s) on male</i>
Heat	Damaged sperm chromatin and quality
Microwaves	Decreased sperm number
Radiation	High doses: death of stem cells and permanent azoospermia
Stray voltage (AC and DC)	Decreased sperm number
<i>Physiological factors</i>	<i>Observed effect(s) on male</i>
Stress	Decreased sperm motility
Fever (hyperthermia)	Damaged sperm chromatin and quality

This table was adapted, with permission, from Ellington and Wilker (2006).

affect the ability of spermatozoa to fertilize ova, but this effect, like others associated with lead exposure, appears to be dependent on age and individual variations in susceptibility, adaptation and reversibility (Sokol, 2006).

Like lead, cadmium is thought to adversely affect male reproduction by several different mechanisms. With respect to spermatogenesis, the stage of the seminiferous epithelium associated with spermiation appears to be specifically inhibited by cadmium (Thomas, 1995). Cadmium has also been shown to have possible interactions with the hypothalamic–pituitary–gonadal axis (Akinloye *et al.*, 2006). The endothelium of the testicular and epididymal vasculature is extremely susceptible to toxic insult by cadmium, potentially resulting in reduced vascular perfusion and testicular necrosis (Haschek *et al.*, 2010). Cadmium can also alter the actin filaments in the junctional complexes between adjacent Sertoli cells, thereby disrupting the integrity of the blood–testis barrier (Thomas and Thomas, 2001). Cadmium can interfere with the cellular metabolism of zinc, an essential trace element necessary for normal reproductive function, and diets deficient in zinc can predispose individuals to the toxic effects of cadmium (Akinloye *et al.*, 2006). Pre-treatment with zinc has been reported to reduce the incidence of cadmium-induced Leydig cell cytotoxicity and neoplasia (Thomas, 1995).

### Gossypol

Gossypol is a yellow, polyphenolic pigment, which is contained in most of the parts of plants belonging to the *Gossypium* genus and is concentrated in pigment glands within the seeds (Morgan, 2004; Casteel, 2007). Gossypol exists as two isomers (enantiomers) within plants (+ and the more toxic –), and these isomeric forms can be non-toxic and bound to plant proteins or toxic and “free” or unbound (Cheeke, 1998). The concentrations of the toxic free form of gossypol vary widely in whole seeds and meals, with the gossypol in direct solvent-extracted cottonseed meal being much more readily bioavailable than the gossypol contained in whole seeds (Cheeke, 1998; Casteel, 2007).

Gossypol can cause systemic and reproductive disease syndromes, depending on the species of exposed animal and the dosage of free gossypol consumed (Randel *et al.*, 1992). The toxic effects of gossypol are cumulative, and systemic disease, characterized by hepatic, renal, cardiovascular and pulmonary abnormalities, is generally observed in monogastric animals (Cheeke, 1998). Mature ruminants are considered to be relatively resistant to the severe systemic effects of free gossypol because of the propensity of this form of the pigment to become bound to proteins in ruminal fluid and, therefore, “detoxified” (Casteel, 2007). Gossypol-induced male subfertility has

been observed in monogastrics and, especially, ruminant species and is dependent on the dosage of free gossypol and the duration of gossypol exposure (Randel *et al.*, 1992; Cheeke, 1998).

Exposure of peri-pubertal or sexually mature males to sufficient dosages of free gossypol adversely affects the seminiferous epithelium and disrupts normal spermiogenesis, resulting in spermatozoa with aplastic midpieces (i.e., segmental aplasia of the mitochondrial sheath) (Randel *et al.*, 1992; Chenoweth *et al.*, 2000). Additional sperm abnormalities, possibly associated with gossypol-induced oxidative damage (Velasquez-Pereira *et al.*, 1998), can potentially develop as stressors related to the acquisition of motility in the epididymidis, and alter the structural integrity of already weakened spermatozoa (Chenoweth *et al.*, 2000). The spermatozoal abnormalities induced by exposure of immature bulls to free gossypol are most likely reversible (Hassan *et al.*, 2004) and can be ameliorated by concurrent treatment with vitamin E (Velasquez-Pereira *et al.*, 1998). Total dietary concentrations of free gossypol supplied as cottonseed meal or whole cottonseed should not exceed 150 and 600 ppm, respectively, in young developing bulls, or, similarly, 200 and 900 ppm in sexually mature animals (Morgan, 2004).

#### *Xenoestrogens and antiestrogens*

Reproductive function in sexually mature males can potentially be adversely affected by exposures to nuclear ER agonists or antagonists, as well as by estrogenic or antiestrogenic EDCs acting independently of receptor-mediated interactions (Evans, 2011b). However, it is clear from the feminizing effects of prenatal exposures to DES (McLachlan, 2001; Newbold *et al.*, 2006) and observations of androgyneization in wildlife species (Edwards *et al.*, 2006) that the male fetus is much more sensitive to the adverse effects of endocrine disruptors than male animals during the postnatal period (Hess and Iguchi, 2002). It is also important to remember that, even in males, xenobiotics which interfere with estrogenic signaling pathways can adversely affect normal reproductive development and function (O'Donnell *et al.*, 2001; Hess, 2003).

#### *Xenoandrogens and antiandrogens*

Normal phenotypic sexual differentiation of the male fetus, as well as all of the postnatal events which result in the delivery of fertile spermatozoa to the female reproductive tract, is dependent on appropriately timed androgenic stimulation of the male. It has been well recognized for quite some time that xenoandrogens (e.g., anabolic steroids and exogenous testosterone and DHT) can interfere with hypothalamic-pituitary-gonadal feedback mechanisms (Figure 19.2), resulting in decreased LH release, sperm abnormalities and testicular atrophy (Ellington and Wilker, 2006). In recent years, there has

been increasing interest in xenobiotics which can interfere with interactions between androgens and their receptors or, in some other way, disrupt androgen-dependent signaling pathways. The dicarboximide fungicides vinclozolin and procymidone and/or their metabolites inhibit the binding of androgens to nuclear androgen receptors and can demasculinize and feminize the prenatally exposed male fetus or induce important alterations in pre- or peri-pubertally exposed offspring (Monosson *et al.*, 1999; Gray *et al.*, 2006). Vinclozolin has also recently been shown to be capable, in some experimental settings, of inducing epigenetic modifications which facilitate the occurrence of transgenerational or vertically transmitted reproductive abnormalities (Anway *et al.*, 2005; Anway and Skinner, 2006). Other potential EDCs, including linuron, *p,p'*-DDE (another metabolite of DDT), prochloraz and, more recently, pyrethroid insecticides can also function as androgen receptor antagonists, with PBDEs acting as competitive inhibitors of the androgen receptor as well as androgen-induced gene expression (Gray *et al.*, 2006; Zhang, 2008; Evans, 2011b). The AhR-mediated effects of TCDD can interfere with the biosynthesis of testosterone and disrupt testosterone signal transduction pathways (Jana *et al.*, 1999; Sikka *et al.*, 2005).

#### *Phthalates*

It is recognized that phthalates, which are used as plasticizers and which are abundant within the environment, share a unique antiandrogenic mechanism, which can result in reproductive dysgenesis in male offspring. Unlike vinclozolin, phthalates are not androgen receptor antagonists, but it is also clear that they are not uterotrophic nor are they capable of inducing a persistent estrus, as would be expected with estrogenic EDCs (Gray *et al.*, 2006). Phthalates actually alter fetal Leydig cell function, resulting in decreased testosterone synthesis and down-regulated expression of insulin-like peptide-3, which is required for gubernacular cords formation (Foster, 2006; Gray *et al.*, 2006; Foster and Gray, 2008). Appropriately timed fetal exposure to di (*n*-butyl) phthalate can result in an abnormal aggregation of Leydig cells in the fetal rat testis, resulting in a failure of Sertoli cell proliferation and functional maturation, similar to what has been proposed as a possible mechanism the development of TDS in humans (Sharpe *et al.*, 2003; Mahood *et al.*, 2005, 2006).

### **Toxicants affecting the female reproductive function**

There have been many documented reports of female reproductive abnormalities associated with exposures of domestic animal species to naturally occurring EDCs

(i.e., phytoestrogens and zearalenone) (Evans, 2011a). Likewise, the adverse endocrine disruptive effects of the ergot alkaloids produced by the tall fescue endophyte *Neotyphodium coenophialum* are also very well understood (Evans *et al.*, 2004; see Chapter 87 in this book). Unfortunately, however, there are still instances of toxicant-induced subfertility which very likely go unrecognized. An effort will be made to review some of the major mechanisms of action for toxic insult to the female reproductive tract in domestic animals, in the hope that the reader might better understand the potential scope of xenobiotic-induced reproductive effects.

### **Selected female reproductive toxicants and mechanisms of action**

#### *Cell-specific reproductive toxicants*

In general, the effects of toxicants on specific cell types within the female reproductive tract, and especially the ovaries, are not as well understood as they are in the testes (Thomas and Thomas, 2001). Many female reproductive toxicants do not target particular cell lines *per se*, but, rather, disrupt the endocrine milieu of the tubular genitalia or cause changes in ovarian structures secondary to alterations in the hypothalamic–pituitary–gonadal axis (Haschek *et al.*, 2010). There are, however, a number of xenobiotics considered to be “ovotoxic.” Phthalates and TCDD can delay or decrease ovulations (Devine and Hoyer, 2005). Ionizing radiation and some of the same chemotherapeutic agents reported to adversely affect rapidly dividing germ cells within the testes (e.g., cyclophosphamide, nitrogen mustard and vinblastine) can also adversely affect primordial follicles within the ovary (Thomas and Thomas, 2001; Devine and Hoyer, 2005). Several PAHs (i.e., BaP, 3-methylcholanthrene (3-MC) and DMBA) and 1,3-butadiene appear to target oocytes in preantral follicles, and DMBA, BaP and 1- and 2-bromopropane, as well as 1,2-dibromopropane, can adversely affect antral follicular development (Devine and Hoyer, 2005). Exposure to free gossypol has been associated with increased numbers of degenerating embryos in heifers (Casteel, 2007).

Like the testes, the ovaries also have some xenobiotic biotransformation capabilities (Thomas and Thomas, 2001; Haschek *et al.*, 2010). As in other organs, oxidative damage can adversely affect ovarian structure and function. In the case of 1,3-butadiene and 4-vinylcyclohexene, the adverse effects of these toxicants on small and growing follicles are due, in part, to the toxic actions of the epoxidated metabolites of these xenobiotics (Devine and Hoyer, 2005).

#### *Heavy metals*

The ovaries do not appear to be as sensitive to the toxic effects of heavy metals as do the testes, and those

adverse effects which are observed are more subject to variation between species than what was observed in the male gonads (Thomas, 1995). Anterior pituitary release of FSH and LH and ovarian steroidogenesis appear to be inhibited by cadmium in the female (Hoyer, 2006). With respect to lead, the neuroendocrine function of the hypothalamic–pituitary–gonadal axis appears to be targeted by lead in the female, as well as in the male (Thomas, 1995; Hoyer, 2006).

#### *Phytoestrogens*

Several genera of leguminous plants produce estrogenic compounds collectively referred to as “phytoestrogens,” which can be associated with clinically relevant effects in livestock species and companion animals. Species of clover, including subterranean clover (*Trifolium subterraneum*), red clover (*Trifolium pratense*), white clover (*Trifolium repens*) and alsike clover (*Trifolium hybridum*), contain phytoestrogens classified as isoflavones (Cheeke, 1998; Burrows and Tyrl, 2001; Mostrom and Evans, 2011; Evans, 2011a). It should also be noted that other leguminous plants, such as soybean (*Glycine max*), which is commonly used as a feed source for agricultural animals, can contain varying amounts of isoflavones. Alfalfa (*Medicago sativa*) contains another class of phytoestrogenic compounds referred to as coumestans (Cheeke, 1998; Mostrom and Evans, 2011).

The relatively inactive, “parent” glycosides for the most clinically relevant isoflavones in clover are formononetin, biochanin A and genestin, and the total concentration of these phytoestrogens can be as high as 2 to 4% (20,000–40,000 ppm) in clover (Burrows and Tyrl, 2001). Primarily within the gastrointestinal tract and, especially, the rumen, formononetin is converted into an intermediate metabolite, daidzein, and, then subsequently into the more estrogenically active phytoestrogen, equol (Cheeke, 1998; Burrows and Tyrl, 2001). Conversely, biochanin A and genestin are initially converted into genestein and then subsequently into estrogenically inactive phenolic compounds (i.e., phenolic acid and *p*-ethylphenol).

Coumestrol is the primary phytoestrogen in alfalfa. This compound has significantly greater estrogenic activity than many of the isoflavones present in other legumes, and this activity generally decreases during the drying process involved in hay production (Cheeke, 1998; Burrows and Tyrl, 2001). Coumestrol is usually only present at very low concentrations (10 to 20 ppm) in the vegetative stages of alfalfa growth, but its estrogenic activity can vary with plant maturity and from year to year (Burrows and Tyrl, 2001; Mostrom and Evans, 2011; Evans, 2011a).

A number of clinical syndromes have been associated with phytoestrogen exposure in domestic animals.

Precocious mammary development has been reported in several instances of phytoestrogen exposure and can be especially evident in dairy breeds of cattle and goats (Evans, 2011a). "Clover disease" in sheep and, to a lesser extent, cattle is associated with the consumption of the isoflavones in clover, resulting in infertility associated with abnormal estrous cycles and structural and functional changes in the cervix (Cheeke, 1998; Burrows and Tyrl, 2001). Phytoestrogen-induced alterations in ovine cervical mucus interfere with the slow, sustained transport of motile spermatozoa from their cervical reservoirs (Cheeke, 1998). Genestein can induce structural changes and, possibly, irreversible organizational abnormalities in the cervix and uterus of exposed gilts (Ford *et al.*, 2006). Coumestan exposure in cattle can be associated with various and, sometimes, seemingly conflicting clinical presentations (e.g., hyperestrogenism, nymphomania, swelling of the external genitalia, estrus suppression, inhibition of ovulation and cystic ovarian disease) (Cheeke, 1998; Casteel, 2007). It is important to remember, particularly when clinical signs are very different from what was anticipated, that phytoestrogens, like other xenoestrogens, can function also as antiestrogens through the inhibition of LH and FSH release from the anterior pituitary and by competing with endogenous estrogens for receptor sites within the tubular genitalia (Cheeke, 1998; Evans, 2011b).

#### *Zearalenone*

The estrogenic mycotoxin zearalenone is produced by *Fusarium graminearum* (formerly *Fusarium roseum*), under certain environmental and storage conditions and, sometimes, in conjunction with vomitoxin or deoxynivalenol (DON). Cereal grains associated with zearalenone production include corn, wheat, barley and oats, and some grasses in New Zealand have also been reported to have been contaminated with zearalenone (Cheeke, 1998). Swine have been shown to be particularly susceptible to the adverse effects of zearalenone, with pre-pubertal gilts being affected by concentrations of zearalenone in the feed as low as 1 to 3 ppm (Cheeke, 1998; Casteel, 2007). The increased sensitivity of pigs to the estrogenic effects of zearalenone is most likely related to the slow metabolism and enhanced enterohepatic recirculation of zearalenone noted in this particular species (Cheeke, 1998). Cattle and other ruminants can be affected by zearalenone but only at dietary concentrations much higher than those associated with clinical signs in swine (Casteel, 2007). Hyperestrogenism in pre-pubertal gilts is characterized by swelling of the vulva and mammary glands, uterine enlargement and ovarian atrophy, and testicular atrophy and preputial swelling have been observed in immature male swine (Cheeke, 1998). As with other xenoestrogens, interference with estrogenic feedback mechanisms and various ovarian abnormalities,

including follicular cysts, have been observed with excessive exposure to zearalenone. Since estrogens are luteotrophic in swine, zearalenone can be associated with prolonged luteal phases (pseudopregnancy), as well as nymphomania in cycling gilts and sows, depending on the phase of the estrous cycle at the time of exposure.

#### *Synthetic xenoestrogens and antiestrogens*

A wide range of agricultural and industrial chemicals, as well as pharmaceuticals used in birth control preparations, have estrogenic and/or antiestrogenic activities, depending on the endocrine environment, presence of endogenous estrogens and stage of development at the time of exposure. The type of tissue and physiological response being discussed, as well as the relative distribution of ER $\alpha$  and ER $\beta$  receptors, will also affect the types of endocrine effects observed in a given circumstance. As has been emphasized previously, the developing fetus is particularly susceptible to the adverse effects of estrogenic and antiestrogenic endocrine disruptors (Hess and Iguchi, 2002).

Some of the synthetic xenobiotics most commonly discussed with respect to their estrogenic and/or, in some instances, their antiestrogenic activity include DES, DDT, PCBs, bisphenol A, nonylphenol, kepone and TCDD (MacLachlan, 2001). While the overall adverse effects of xenoestrogens have already been discussed in this chapter with respect to reproductive development and endocrine disruption, there are several unique clinical aspects of exposures to these types of xenobiotics which should be addressed for completeness. Prenatal human exposures to the synthetic, non-steroidal xenoestrogen DES have been associated with feminization of the male fetus, as well the increased occurrence of clear cell adenocarcinoma of the vagina in young women (McLachlan 2001; McLachlan *et al.*, 2006; Newbold *et al.*, 2006; Rogers and Kavlock, 2008). The use of DES for mismating or pregnancy prevention in dogs has been, in some instances, associated with an increased incidence of cystic endometrial hyperplasia and pyometra. The apparent ability of the widely distributed xenoestrogen bisphenol A to cause adverse developmental effects at very low environmental concentrations and in a manner characterized by a non-monotonic (inverted U- or U-shaped) dose response has been difficult for some researchers to reproduce and remains controversial (Welshons *et al.*, 2006). However, this particular issue is worthy of further, detailed discussions regarding appropriate reproductive endpoints and necessary experimental controls, given the topic's scientific ramifications, societal relevance and potential applications to other EDCs (Evans, 2011b).

#### *Xenoandrogens*

While the emphasis in the area of endocrine disruption has traditionally been on the adverse effects of

xenoestrogen reproductive development and function, there is increasing evidence that there are also instances of endocrine disruptors having androgenic activity. The effluents from pulp and paper mills have recently been shown to be able to masculinize female fish (Gray *et al.*, 2006). In addition, the runoff from cattle feedlots, where the synthetic androgen trenbolone was used for the promotion of growth, has also been shown to have androgenic activity and is also suspected of being associated with masculinization of females in wildlife species (Orlando *et al.*, 2004).

## Teratogenesis and abortion

### *Mechanisms of actions of teratogenesis and abortion*

A large number of xenobiotics have been classified with respect to their teratogenic potential, and these are listed in Table 19.2. The ability of EDCs to interfere with phenotypic sexual differentiation in the fetus has already been extensively reviewed in this chapter. Teratogenesis can be associated with each of the following mechanisms of action: (1) excessive cell death; (2) interference with apoptosis; (3) reduced cellular proliferation rate; (4) failed interactions between cells; (5) impaired morphogenetic movements; (6) reduced synthesis of components essential for growth and development; (7) mechanical disruption; (8) and alterations in pH (Hood *et al.*, 2002; Hood, 2006). Some teratogens are capable of more than one mechanism of action. Premature parturition or abortion can be induced by any xenobiotics which cause fetal or, potentially, maternal stress and initiate the cascade of endocrine and neural signaling events which would normally lead to parturition. Any intoxication in a pregnant animal has the potential to threaten fetal survival. Toxicants which cause sudden fetal death or complete cessation of placental function or disruption of the gestational source of progestagens can also induce abortion in animals.

### *Heavy metals*

Several heavy metals have been identified as teratogens and possible abortifacients in humans and animals. The adverse effects of *in utero* lead exposure, on the developing nervous systems of both humans and laboratory animal species, have been well documented (Evans *et al.*, 2003; Rogers and Kavlock, 2008). Prenatal exposure to organotins has been associated with pregnancy loss and impaired ossification in rodents (Ema and Hirose, 2006), and organic mercury is a known developmental neurotoxicant (Golub, 2006b). Other heavy metals, including cadmium and mercury, have been associated with placental toxicity, and this topic is covered in greater detail in Chapter 20 of this book.

### *Selected plant-associated teratogens and abortifacients*

Many potentially toxic plants have been found to induce teratogenesis and/or abortion in mammals, including swainsonine-containing species of *Astragalus* and *Oxytropis* and plants associated with nitrate/nitrite intoxication. While it is not possible to extensively review all of these plants in this chapter, there are several well-documented examples of plant-induced birth defects and abortion which clearly illustrate the basic principles regarding the pathogenesis of teratogenesis and abortion in domestic animals. There are a number of references which review the adverse effects of specific plants and/or toxicants on reproduction in some detail (Burrows and Tyrl, 2001; Evans, 2011a; Panter and Stegelmeier, 2011; Panter *et al.*, 2011).

### *Veratrum californicum*

Jervanine alkaloids (e.g., cyclopamine, cycloposine and jervine) in *Veratrum californicum* (false hellebore) and, potentially, some closely related plants have been associated with the occurrence of cyclops lambs and other developmental abnormalities in sheep, as well as, less commonly, cattle and goats (Burrows and Tyrl, 2001; Panter and Stegelmeier, 2011; Panter *et al.*, 2011). The mechanism of action of the teratogenic alkaloids in species of *Veratrum* involves interference with the *sonic hedgehog* (SHH) signal transduction pathway and the inhibition of neuroepithelial cell mitosis and migration during neurulation and decreased proliferation of chondrocytes (Cheeke, 1998; Burrows and Tyrl, 2001; Panter and Stegelmeier, 2011). The specific developmental abnormalities and the precise timing of maternal exposure to *Veratrum californicum*, which results in these defects is as follows: cyclops lambs and prolonged gestation (associated with the absence of pituitary gland) from maternal exposure on days 12 to, particularly, day 14 of gestation; embryonic death from maternal exposure on gestational days 19 to 21; cleft palate from maternal exposure on gestational days 24 to 30, metacarpal and metatarsal defects (limb reductions) and tracheal cartilage defects (tracheal stenosis) from maternal exposure on gestational days 28 to 31 and 31 to 33, respectively (Burrows and Tyrl, 2001). No abnormal effects were observed with maternal exposure to *Veratrum californicum* before day 10 or after day 35 of pregnancy, and *Veratrum*-associated birth defects can generally be prevented by avoiding exposure until at least 5 weeks after breeding.

### *Multiple congenital contractures*

Species of tobacco (*Nicotiana* spp.), poison hemlock (*Conium maculatum*) and lupines (*Lupinus* spp.) have all been shown to be able to induce MCC or "crooked calf

TABLE 19.2 Safety of drugs in pregnancy

Drug	Recommendation	Comments
<i>Antimicrobial drugs</i>		
Amikacin	C	Aminoglycoside antibiotics easily cross the placenta and may cause 8th nerve toxicity or nephrotoxicity.
Ampicillin	A	Crosses the placenta but has not been shown to be harmful to fetus.
Amoxicillin	A	Crosses the placenta but has not been shown to be harmful to fetus.
Carbenicillin	A	Crosses the placenta but has not been shown to be harmful to fetus.
Cephalosporins	A	Crosses the placenta but has not been shown to be harmful to fetus.
Chloramphenicol	C	May decrease protein synthesis in fetus, particularly in bone marrow.
Ciprofloxacin	D	Do not use during pregnancy; quinolones have been associated with articular cartilage defects.
Clavulanic acid–amoxicillin (Clavamox, Beecham)	A	Crosses the placenta but has not been shown to be harmful to fetus.
Clindamycin	A	Crosses the placenta but has not been shown to be harmful to fetus.
Cloxacillin	A	Crosses the placenta but has not been shown to be harmful to fetus.
Dicloxacillin	A	Crosses the placenta but has not been shown to be harmful to fetus.
Doxycycline	D	Tetracyclines can cause bone and teeth malformations in fetus and may cause toxicity in mother.
Enrofloxacin	D	See ciprofloxacin.
Erythromycin	A	Appears to be safe except for erythromycin estolate, which has been shown to increase the risk of hepatotoxicity in women.
Gentamicin	C	Aminoglycoside antibiotics easily cross the placenta and may cause 8th nerve toxicity or nephrotoxicity. However, specific toxicities from gentamicin have not been reported, and it may be used for a serious infection in place of a suitable alternative.
Hetacillin	A	Crosses the placenta but has not been shown to be harmful to fetus.
Kanamycin	C	Aminoglycoside antibiotics easily cross the placenta and may cause 8th nerve toxicity or nephrotoxicity.
Lincomycin	A	Crosses the placenta but has not been shown to cause problems in fetus.
Metronidazole	C	Teratogenic in laboratory animals, but there is no information for dogs and cats. It should be avoided during the first 3 weeks of pregnancy.
Neomycin	A	Not absorbed sufficiently to cause systemic effects after oral administration.
Oxacillin	A	Crosses the placenta but has not been shown to be harmful to fetus.
Oxytetracycline	D	Toxic to fetus and may increase risk of hepatitis in mother (see tetracycline).
Penicillin G (benzyl penicillin)	A	Crosses the placenta but has not been shown to be harmful to fetus.
Streptomycin	D	See gentamicin. Streptomycin is associated with higher incidence of 8th nerve toxicity than other aminoglycosides.
Sulfonamides	B	Sulfonamides cross the placenta and have produced congenital malformations in rats and mice, but problems have not been reported in dogs or cats; in people, they have caused neonatal icterus when administered near term. Avoid long-acting sulfonamides.
Tetracycline	D	Tetracyclines can cause bone and teeth malformations in fetus and may cause toxicity in mother.
Trimethoprim–sulfadiazine (Tribrissen, Coopers)	B	Manufacturer states that it is safe during pregnancy in dogs; see also trimethoprim and sulfonamides.
Trimethoprim	B	Teratogenic in rats but probably safe in other species. Folate antagonism and bone marrow depression are possible with prolonged use.
Ticarcillin	A	Crosses the placenta but has not been shown to be harmful to fetus.
Tobramycin	C	Aminoglycoside antibiotics easily cross the placenta and may cause 8th nerve toxicity or nephrotoxicity.
Tylosin	B	No information is available.
<i>Antifungal drugs</i>		
Amphotericin-B	C	There are no known teratogenic effects, but amphotericin is extremely toxic. Use only if the disease is life threatening, in absence of a suitable alternative.
Griseofulvin	D	Teratogenic in rats; causes multiple skeletal and brain malformations in cats.
Ketoconazole	B	Teratogenic and embryotoxic in rats; antiandrogenic; stillbirths have been reported in dogs.
Miconazole	A	Apparently safe if applied topically.
<i>Antiparasitic drugs</i>		
Amitraz	C	Manufacturer states that reproduction studies have not been done; no information available.
Diethylcarbamazine	A	Manufacturer states that the drug may be given to dogs throughout gestation.
Dithiazanine iodide (Dizan, TechAmerica)	B	No information is available; iodide salts may cause congenital goiter if administered for prolonged periods during pregnancy.

(Continued)

TABLE 19.2 (Continued)

Drug	Recommendation	Comments
Fenbendazole	A	Safe. Has been administered to pregnant bitches without producing adverse effects.
Dichlorvos (Task, Solvay)	B	Caution is advised when administering cholinesterase inhibitors to pregnant animals; it should not be administered to puppies or kittens, but studies in pregnant dogs and cats suggest that there are no adverse effects during pregnancy.
Ivermectin	A	Safe. Reproduction studies in dogs, cattle, horses and pigs have not shown adverse effects.
Levamisole	C	No information available.
Mebendazole	A	Safe. In reproduction studies in dogs, it was not teratogenic or embryotoxic.
Piperazine	A	Safe. No known contraindications for the use of piperazine.
Praziquantel	A	Safe. No adverse effects were seen when tested in pregnant dogs and cats.
Thiacetarsamide (Caparsolate sodium, CEVA)	C	No specific information regarding toxicity to fetus is available. It can be hepatotoxic and nephrotoxic, and heartworm adulticide should be postponed until after parturition.
Bunamidine	A	Has been administered to pregnant bitches without problems and is safe in pregnant cats. Slight interference with spermatogenesis has been seen in male dogs.
Pyrantel	A	Safe. Toxicity studies have not shown any adverse effects.
Thienium	A	Safe. Manufacturer states that except in young puppies, there are no known contraindications.
Thiabendazole	B	Thiabendazole is not teratogenic in laboratory animals, but high doses have produced toxemia in ewes.
Trichlorfon	C	Caution is advised when administering organophosphates to pregnant animals. Congenital toxicoses have been reported following administration to pregnant sows. Manufacturer states that trichlorfon should not be administered to pregnant mares, but there are no recommendations for dogs and cats.
<i>Anticancer drugs</i>		
Doxorubicin hydrochloride (Adriamycin, Adria)	C	May produce malformations in newborn or embryotoxicity.
Azathioprine	C	May produce congenital malformations but has been used in pregnant women safely. It may be a suitable alternative to other drugs when immunosuppressive therapy is required.
Chlorambucil	C	May produce malformations in newborn or embryotoxicity.
Cisplatin	C	May produce congenital malformations, embryotoxicity or nephrotoxicity.
Cyclophosphamide	C	May produce malformations in newborn or embryotoxicity.
Methotrexate	C	May produce malformations in newborn or embryotoxicity.
Vincristine	C	May produce malformations in newborn or embryotoxicity.
<i>Analgesic drugs</i>		
Acetaminophen	C	Safety not established in dogs; toxic in cats.
Aspirin	C	Embryotoxicity has been seen in laboratory animals but not in other species. Late in pregnancy, it may produce pulmonary hypertension and bleeding problems (see text).
Flunixin meglumine	C	Safety in pregnancy has not been determined.
Gold (aurothioglucose)	D	Laboratory animal studies clearly show increased congenital malformations.
Ibuprofen	C	Safety in dogs and cats not established.
Indomethacin	C	Can be toxic in adult dogs; can cause premature closure of ductus arteriosus if administered near term.
Phenylbutazone	C	Safety has not been established. Long-term use can depress bone marrow.
Salicylates	C	Embryotoxicity has been seen in laboratory animals but not in other species. Late in pregnancy, it may produce pulmonary hypertension and bleeding disorders.
<i>Anesthetic and preanesthetic drugs</i>		
Acepromazine	B	Phenothiazines should be avoided near term; they may produce neonatal CNS depression.
Atropine	B	Crosses the placenta and has been used safely but may cause fetal tachycardia.
Butorphanol	B	Safe for short-term use. Neonatal depression can be treated with naloxone.
Codeine	B	Safe for short-term use. Neonatal depression can be treated with naloxone.
Diazepam	C	See anticonvulsants.
Fentanyl	B	Safe for short-term use. Neonatal depression can be treated with naloxone.
Glycopyrrolate	B	Safe. Does not cross placenta as readily as atropine. Studies in rats and rabbits have not revealed teratogenic effects.
Halothane	C	Decreased learning ability has been reported in rats after <i>in utero</i> exposure; depression may be seen in neonates after cesarean section; excessive uterine bleeding may be seen when administered during cesarean section.
Isoflurane	B	Probably safe. Depression may be seen in neonates after cesarean section.

(Continued)

TABLE 19.2 (Continued)

Drug	Recommendation	Comments
Ketamine	B	Probably safe. Depression may be seen in puppies delivered by cesarean section; may increase intrauterine pressure and induce premature labor.
Lidocaine	A	All local anesthetics appear to be safe when used for a local nerve block or epidural anesthesia.
Meperidine	B	Opiates can produce neonatal sedation and respiratory depression, but the effects can be reversed with the administration of naloxone.
Methoxyflurane	C	Neonatal depression is seen when used for cesarean section.
Morphine	B	Opiates can produce neonatal sedation and respiratory depression, but the effects can be reversed with the administration of naloxone.
Naloxone	A	Has been shown to be safe when administered to newborns within a few minutes after birth.
Nitrous oxide	B	Probably safe. Used frequently for cesarean section without adverse effects.
Oxymorphone	B	Opiates can produce neonatal sedation and respiratory depression, but the effects can be reversed with the administration of naloxone.
Pentobarbital	D	Associated with high incidence of neonatal mortality.
Thiamylal	C	Easily crosses the placenta; all barbiturates produce respiratory depression in fetus; however, thiobarbiturates are not as toxic as pentobarbital.
Thiopental	C	Easily crosses the placenta. All barbiturates produce respiratory depression in fetus; however, thiobarbiturates are not as toxic as pentobarbital.
<i>Gastrointestinal drugs</i>		
Antacids	A	Safe. Not absorbed systemically.
Antiemetics	B	Probably safe if administered short term.
Cimetidine	B	Safety has not been established, but no reports of toxicity in humans.
Dimenhydrinate	B	Safe if used short term.
Diphenhydramine	B	Safe if used short term.
Diphenoxylate	C	Studies have reported adverse effects in laboratory animals, but no adverse effects have been reported in pregnant dogs, cats and humans.
Laxatives	B	All laxatives, except castor oil (Squibb), are considered safe if they are used short term. Castor oil causes premature uterine contractions.
Loperamide	C	Same comment as diphenoxylate.
Metoclopramide	B	Safe in laboratory animals, but no studies available for cats or dogs.
Methscopolamine	C	Safety not established.
Misoprostol	D	Synthetic prostaglandin, causes a termination of pregnancy.
Prochlorperazine	B	No reports of toxicity when administered short term.
Ranitidine	B	Safety has not been established, but no reports of toxicity were reported in humans.
Sucralfate	A	Probably safe. Not absorbed systemically.
Sulfasalazine	B	Salicylate component is not absorbed enough to produce adverse effects; sulfonamide may produce neonatal icterus when used near term (see text).
<i>Cardiovascular drugs</i>		
Atropine	B	Probably safe but may produce fetal tachycardia.
Captopril	C	Has been shown to be embryotoxic in laboratory animals and goats.
Digitalis	A	Probably safe. No adverse effects seen in humans and laboratory animals (see text).
Furosemide	B	No adverse effects have been reported.
Dopamine	B	Probably safe at therapeutic doses.
Heparin	B	Does not appear to cross placenta.
Hydralazine	B	Probably safe. There have been reports of minor toxicity in rats, but it has been administered safely to pregnant women.
Isoproterenol	C	May cause fetal tachycardia; beta-adrenergic drugs inhibit uterine contractions.
Lidocaine	B	Probably safe. May cause fetal bradycardia.
Nitroglycerin	C	No information available.
Nitroprusside	C	There is a risk of fetal cyanide toxicity with prolonged use.
Procainamide	B	Probably safe. May cause fetal bradycardia.
Propranolol	C	May cause fetal bradycardia, respiratory depression and neonatal hypoglycemia; avoid use near term.
Quinidine	B	Probably safe. May cause fetal bradycardia.
Theophylline	B	No reports of adverse effects.
Thiazide diuretics	C	May cause increased incidence of perinatal mortality.
Warfarin	D	Causes embryotoxicity and congenital malformations, neural tube defects in laboratory animals and humans.
<i>Anticonvulsant drugs</i>		
Diazepam	C	Has been associated with congenital defects in mice, rats and people.

(Continued)

TABLE 19.2 (Continued)

Drug	Recommendation	Comments
Phenobarbital	B	Has been associated with rare congenital defects and bleeding tendencies in newborn but may be safer than other anticonvulsants (see text).
Phenytoin	C	Teratogenic in rats, mice and people.
Primidone	C	Same risks as phenobarbital and has been associated with increased incidence of hepatitis in adult dogs.
Valproic acid	C	May cause congenital malformations.
<i>Muscle relaxants</i>		
Dantrolene	C	Safety not established.
Dimethyltubocurarine	B	Quarternary base with negligible placental transfer; it does not affect the fetus unless administered in large doses.
Gallamine	B	Quarternary base with negligible placental transfer; it does not affect the fetus unless administered in large doses.
Methocarbamol	C	Safety not established; manufacturer states that it should not be administered during pregnancy.
Pancuronium	B	Quarternary base with negligible placental transfer; it does not affect the fetus unless administered in large doses.
Succinylcholine	B	Quarternary base with negligible placental transfer; it does not affect the fetus unless administered in large doses.
<i>Endocrine drugs</i>		
Betamethasone	C	Corticosteroids have been associated with increased incidence of cleft palate and other congenital malformations, and they may induce premature labor and abortion in dogs (see text).
Cortisone	C	Corticosteroids have been associated with increased incidence of cleft palate and other congenital malformations, and they may induce premature labor and abortion in dogs (see text).
Dexamethasone	C	Corticosteroids have been associated with increased incidence of cleft palate and other congenital malformations, and they may induce premature labor (see text). Dexamethasone has caused abortion and fetal death in dogs.
Diethylstilberstrol (DES)	D	Malformation of male and female genitourinary systems.
Estradiolcypionate (ECP)	D	Malformation of male and female genital tracts and bone marrow depression.
Flumethasone	C	Corticosteroids have been associated with increased incidence of cleft palate and other congenital malformations, and they may induce premature labor and abortion in dogs (see text).
Mitotane ( <i>o,p'</i> -DDD)	D	Adrenocortical necrosis.
Prednisolone	C	Although prednisolone has been administered to pregnant women without adverse effects, caution is advised (see dexamethasone). Prednisolone may be used in serious diseases in absence of a suitable alternative.
Stanozolol	D	Manufacturer states that it should not be administered to pregnant dogs and cats.
Testosterone	D	Causes masculinization of female fetus.
Thyroxine	B	Does not cross placenta easily and has not been associated with any problems.
<i>Miscellaneous drugs</i>		
Ammonium chloride	B	May cause fetal acidosis; discontinue use during pregnancy.
Aspartame (Nutra Sweet)	A	No risk.
Dimethylsulfoxide (DMSO)	C	Teratogenic in laboratory animals; manufacturers state that it should not be applied to breeding animals.

A: Probably safe. Although specific studies may not have proved the safety of all drugs in dogs and cats, there are no reports of adverse effects in laboratory animals or in women.

B: Safe for use if used cautiously. Studies in laboratory animals may have uncovered some risk, but these drugs appear to be safe in dogs and cats or these drugs are safe if they are not administered when the animal is near term.

C: These drugs may have potential risks. Studies in people or laboratory animals have uncovered risks, and these drugs should be used cautiously, as a last resort when the benefit of therapy clearly outweighs the risks.

D: Contraindicated. These drugs have been shown to cause congenital malformations or embryotoxicity.

disease" in cattle and, potentially, other species exposed to their toxic principles at the appropriate stage of gestation. The condition is characterized by cleft palate and limb and spinal contractures. Pyridine alkaloids (e.g., anabasine) in tobacco, piperidine alkaloids in poison hemlock (e.g., coniine and  $\gamma$ -coniceine) and piperidine-derived and quinolizidine alkaloids in lupines

(e.g., ammodendrine and anagyrine, respectively) cause stimulation then depression (depolarizing neuromuscular blockade) of nicotinic receptors in the fetus (Cheeke, 1998; Burrows and Tyrl, 2001; Panter, 2002). This stimulation followed by neuromuscular blockade of fetal nicotinic receptors during the critical period of palate and joint development (i.e., gestational days 40 to 100

in cattle; days 30 to 60 in sheep; days 30 to 60 in swine) results in decreased fetal movement and the failure of the palate and joints to form in a normal fashion (Panter, 2002; Panter and Stegelmeier, 2011).

#### *Pine needle abortion*

Ingestion by cattle of pine needles (*Pinus ponderosa*) containing isocupressic acid (also possibly present in the vegetation of some junipers and cypresses) results in late-term abortion (Cheeke, 1998). Inhibition of the catechol estrogen-induced blockade of potential-sensitive  $\text{Ca}^{2+}$  channels by isocupressic acid leads to enhanced entry of divalent calcium into arterial smooth muscle cells supplying the gravid uterus and results in profound vasoconstriction (Casteel, 1997; Cheeke, 1998; Burrows and Tyrl, 2001; Panter and Stegelmeier, 2011; Panter *et al.*, 2011). This isocupressic acid-induced vasoconstriction can lead to at least a 50% reduction in the blood flow reaching the fetal circulation and causes fetal stress, leading to the induction of premature parturition or abortion (Cheeke, 1998; Burrows and Tyrl, 2001). Late-term abortion occurs 2–14 days following heavy consumption of green or dry pine needles and results in up to 75% of exposed cows aborting or delivering dead or weak calves (Cheeke, 1998; Burrows and Tyrl, 2001; Casteel, 2007; Panter and Stegelmeier, 2011). Dams are frequently dull and depressed, with weak uterine contractions, incomplete cervical dilation, retained placenta and frequent post-partum metritis (Cheeke, 1998).

## CONCLUDING REMARKS

Reproduction is a critical biological process, required for financially viable livestock production, as well as species survival. Toxicant-induced abortions, congenital defects and subfertility can have devastating effects on both domestic animals and wildlife species. There is growing concern within the scientific and government regulatory communities, and especially the general public, about the potential for these toxicant-induced effects in humans. The information presented in this chapter was intended to familiarize the reader with terminology and concepts pertinent to reproductive toxicity and endocrine disruption, as well as to provide an overview of reproductive development, anatomy and physiology and aspects of these processes susceptible to toxic insult by naturally occurring and synthetic xenobiotics. The information and references provided should assist readers in making informed decisions in the course of their future clinical investigations, experimental designs and interpretations of scientific literature and/or regulatory policies.

## Placental toxicity

Ramesh C. Gupta

### INTRODUCTION

Placental toxicology embraces the knowledge of the responses of the placenta and fetus to chemical insult. It is a fascinating subject, as it deals with three components: mother, placenta and fetus. The subject includes structural and functional changes in the placenta, placentation, implantation, embryotoxicity, fetal resorption, functional deficits, structural malformation, growth retardation and birth defects. Placental toxicology has blossomed and matured in the last several decades from the contributions of scientists around the world. It has received enormous attention from the biologists, pharmacologists, toxicologists, teratologists and regulatory agencies, since the incidence of thalidomide in the 1960s.

The placenta is a rapidly growing organ, with a limited lifespan, which interfaces two separate genomes (mother and fetus). During pregnancy, the placenta serves many functions and undergoes numerous changes, such as the production and release of hormones and enzymes, transport of nutrients and waste products, chemical information flows between mother and fetus, implantation, cellular growth and maturation, at the terminal phase of placental life, and participation in delivery (Pelkonen *et al.*, 2006). In other words, the placenta plays many roles in the development of the fetus by serving as the lung, kidney, gut and exocrine/endocrine glands. Its role in providing nutrients to the developing fetus through maternal circulation has been established for a long time. Unfortunately, some of the toxic metals, such as cadmium and lead, are also delivered to the fetus by the same mechanism as that of the nutrients. In fact, many foreign substances, including pesticides, plant alkaloids, mycotoxins and drugs, reach the fetus with very little or no resistance.

The health of the placenta is a prerequisite for the health of the fetus. In the toxicant-exposed mother, the chemical encounters the placenta before it reaches

the fetus. Therefore, chemical-induced damage in the placenta is likely to reflect in the fetus. In essence, the health of the placenta seems as important as the health of the mother or the fetus. Vulnerability of this organ to toxic effects is enormous, since it has a considerable amount of metabolic activity, and as a result the placenta can enhance the toxicity by forming metabolites of greater toxicity than the parent compounds.

Literature abounds with ample evidence that the poisons of many classes adversely affect the mother and the fetus; however, it is sparse for the placenta. Many toxicants adversely affect fetal growth or survival at doses that do not produce any toxic effects in the mother. The evidence also suggests that malformations result from specific action of chemicals, rather than as a general response to maternal illness. Another important concern that needs to be mentioned is that the mechanism involved in maternal toxicity most often differs from the mechanism involved in fetotoxicity and teratogenicity. Thus, the placenta appears to be a complex organ, as its anatomical, physiological and metabolic characteristics vary depending on the age of the placenta. This would make it important to study placentas from different stages of pregnancy. It is beyond the scope of this chapter to discuss the placental toxicity of every single chemical, instead this chapter is focused on common poisons, such as metals, pesticides, mycotoxins, tobacco, etc. that adversely affect pregnant animals, placenta and fetus.

### ROLE OF THE PLACENTA

The placenta serves pivotal roles in fetal nutrition, respiration and excretion. The placenta also provides protection to the fetus. This organ has a limited lifespan, as the umbilical cord, placenta, amnion and chorion are

expelled soon after the birth of the fetus. For decades, the view of pharmacologists, toxicologists, teratologists and biologists has been that the placenta is a rejected tissue and may not be suitable for bioassay or evaluation of the cellular/molecular mechanisms of actions of drugs and toxic chemicals. But, due to substantial progress in placental pharmacology/toxicology research, the view has changed. Currently, several methods are available to use different parts of the placenta in screening drugs and chemicals and to study the molecular mechanisms for their pharmacological and toxicological effects. Use of pregnant animals is considered the preferred model to assess the toxicological actions of chemicals. In such circumstances, it is important to study placentas from different stages of pregnancy. However, obtaining material for such studies is difficult for practical reasons. Furthermore, in assessing placental toxicity of chemicals, all physiological and anatomical variables should be taken into consideration. In addition, there are several *in vitro* pharmacological/toxicological preparations from the placenta, which include: (1) perfused single placental cotyledon; (2) villus preparation; (3) segments of umbilical, chorionic plate and villus stem arteries and veins; (4) trophoblast plasma membrane; (5) isolated receptors and transporters; and (6) the placenta as a source of stem cells. For further details refer to [Sastry \(1997\)](#), [Pelkonen \*et al.\* \(2006\)](#), [Malek and Mattison \(2010\)](#) and [Dzierzak and Robin \(2010\)](#).

## TYPES OF PLACENTA

The placentas of different species vary in shape, internal architecture and nature of the interhemal barrier. Anatomically, the placenta is a complex organ and is classified into four types: (1) hemochorial (rat, rabbit, human); (2) endotheliochorial (cat, dog); (3) syndesmochorial (ruminants); and (4) epitheliochorial (pig, horse). The placenta has also been described as zonary in the dog, bidiscoid in the monkey and multicotyledonary in the sheep. Placental thickness depends on the number of fetal and maternal cell layers. For example, the rat and rabbit have a single layer of cells, primates and humans have three layers and pigs and horses have six layers. In addition to anatomical, there are physiological and functional differences among different types of placenta. Because of technical and practical advantages, animal placentas have been used to study placental function and pharmacological and toxicological actions. However, the hemochorial placenta has been studied more extensively compared to other types. In the hemochorial placenta, the membrane separating the maternal and fetal compartments consists of three layers (syncytiotrophoblast, connective tissue and vascular fetal endothelium). These anatomical and physiological similarities and differences in placentas of

different species should be taken into consideration when studying and evaluating placental toxicity.

## METABOLISM IN PLACENTA

Both phase I reactions (oxidation, reduction and hydrolysis) and phase II reactions (conjugation of a chemical with endogenous moiety, such as glucuronic acid or sulfate) of metabolism exist in the placenta as well as the fetus. The placenta can also be active in intermediary metabolism, such as gluconeogenesis, urea and fatty acid synthesis. The capacity for metabolic processes appears to vary with species, gender and gestational stage. Carbonic anhydrase activity, a marker of placental metabolism and transfer, is greater in the pig, rat and mink than in the horse, cow and human. Xenobiotic metabolism in the placenta seems to be similar to that in maternal tissues, but the extent of the metabolic activity is usually less. However, the metabolic activity is still enough that the placental/fetal toxicity of chemicals can be significantly modified. The placenta has an abundance of drug- and xenobiotic-metabolizing enzyme systems, i.e., cytochrome P450. Cyt P450 exists in multiple forms with distinct, but generally overlapping, substrate specificities and many of the isoforms are inducible by exposure to exogenous agents ([Pasanen and Pelkonen, 1994](#)). In the placenta, several steroid hormones are formed and metabolized by Cyt P450 systems, which may participate in xenobiotic metabolism. In general, the metabolites produced by biotransformation are usually less toxic compared to the parent compound, and thereby the xenobiotic-metabolizing enzymes in the placenta protect the fetus from potentially fetotoxic drugs and chemical toxicants. It is noteworthy that the same enzyme system can also form metabolites which are more toxic than their parent compounds. For example, oxon metabolites of organophosphorus insecticides and epoxides of cyclodiene chlorinated hydrocarbons have a greater potential for fetotoxicity/teratogenicity than their parental forms. In addition, placental metabolism has the capacity to form carcinogen–DNA adducts. Compared to phase I, phase II reactions in the placenta have not been studied in detail because the placenta contains very low activities of these enzymes.

## PLACENTAL SUSCEPTIBILITY TO TOXICANTS

Since the placenta serves as an exchanger between mother and fetus for nutrients, the health of the fetus

seems to be dependent on the health of the mother and placenta. There appear to be several mechanisms by which toxicants are concentrated in the placenta and fetal tissues in greater quantities than in the maternal tissues. The placenta is highly vascularized tissue with a large surface area that comes in contact with a relatively large volume of maternal blood, which is required for normal placental function, and thereby makes the placenta vulnerable to toxicants. In addition, the placenta has several biomolecules, such as proteins, lipids, carbohydrates, nucleic acids/nucleotides, hormones and growth factors, receptors, and drug-metabolizing and many other enzymes. The placenta, being rich in proteins, bioconcentrates chemical residues by means of protein binding and releases them into the placental circulation and ultimately into the fetus. In essence, the structure and function of the placenta are so unique that its susceptibility to chemical toxicity seems far greater than that of the mother. Thus, any damage to the placenta caused by a toxic chemical is likely to reflect in the fetus.

## PLACENTAL BARRIER FOR CHEMICAL TOXICANTS

The placenta is the entry through which the fetus is exposed to most chemical poisons, and the term placental barrier appears to be a false notion. The placenta has been characterized as a lipid membrane that permits bidirectional transfer of substances between maternal and fetal compartments rather than as a barrier. In general, the placental barrier consists of the trophoblastic epithelium covering the villi, the chorionic connective tissue and the fetal capillary endothelium. Foreign chemicals are transferred through placental membranes by passive diffusion. The two most common factors that are involved in transplacental transfer of common toxicants are: (1) physicochemical properties of the chemical and (2) type of placenta. In general, any chemical with a molecular weight <1000 readily crosses the placenta, and therefore the majority of the chemical toxicants are not restricted from reaching the fetus. It is important to mention that chemical properties, such as lipophilicity, polarity and degree of ionization, can influence the placental barrier. The second factor that predominantly influences the transplacental transfer of chemical toxicants is the type of placenta. For instance, the complex multilayered placenta of higher mammals can make it more difficult for chemicals to gain access to the fetus compared to the simpler choriovitelline or chorioallantoic type of placenta (Ala-Kokko *et al.*, 2000; Pelkonen *et al.*, 2006). A number of other factors that can influence the rate and extent of transplacental transfer of toxicants include: (1) maternal/fetal chemical gradient, (2)

uterine and umbilical blood flow, (3) molecular weight of the chemical, (4) protein binding and (5) lipid solubility. These factors can also determine the time required for maternal/fetal equilibrium of a toxicant. Direct or indirect evidence for placental transfer of chemical toxicants is determined based on residue analysis of these compounds and/or their metabolites in the placenta, umbilical cord and embryo/fetus.

## FACTORS THAT MAY INFLUENCE THE PLACENTAL TOXICITY

Anatomical, physiological and metabolic characteristics vary depending on the stage of the placenta. There are three major factors that can modify the overall toxicity of a chemical during pregnancy: (1) maternal toxicity, (2) placental transfer of a chemical and (3) placental/fetal metabolism.

### Maternal toxicity

Maternal toxicity can be defined as the transitory or permanent state of alteration in maternal physiology or behavior with a potential to cause adverse effects in the offspring during embryo/fetal or postnatal development. The common factors related to maternal toxicity are as follows:

- 1 Route of drug/chemical exposure
- 2 Maternal drug/chemical distribution
- 3 Maternal drug/chemical metabolism
- 4 Uterine blood flow
- 5 pH of the blood

Although the precise mechanism by which maternal toxicity factors are responsible for fetal toxicity or teratogenesis has remained unexplained, alterations in placental function appear to be important. It seems that maternal toxicity plays a major role in adverse fetal outcome by modifying placental function.

### Placental transfer of toxicants

The factors related to placental morphology, physiology and metabolism seem to be interrelated, and with continuing change they become more complex as gestation advances. The important placental transfer factors include:

- 1 Placental blood flow
- 2 pH of the blood

- 3 Placental permeability (passive or active transport system)
- 4 Placental maturity over gestation period (size, surface area and thickness)
- 5 Interspecies variation in placental morphology
- 6 Lipid-protein content of the membranes
- 7 Placental metabolism
- 8 Plasma protein binding
- 9 Physico-chemical properties of toxicants

Plasma protein (mainly albumin) binding appears to be the important factor that can modify placental toxicity. A chemical can cross the placenta only if the chemical is in free form, but a protein-bound form can be released into free form, since the protein binding is a reversible process. Once the chemical has reached the fetus, either it remains free to produce toxic effects, or once again it can bind to proteins of blood or fetal tissues, a phenomenon described as the “sink effect.”

### Placental/Fetal metabolism

Metabolism occurs in all placental and fetal tissues, as it occurs in maternal tissues, but the capacity differs at all stages of gestation. During pregnancy, metabolism of the toxicant is complicated by two major factors: (1) the pregnancy itself, since the general metabolic activity is significantly low, which may lower the degradation of toxicants and thereby increase the toxicity, and (2) pre-exposure or simultaneous exposure to other chemicals or environmental pollutants generally results in either reduced or enhanced metabolism, and consequently alters the placental toxicity. For example, previous exposure to drug-metabolizing enzyme inducers, such as enhanced monooxygenase activity by polychlorinated biphenyls (PCBs) or similar environmental pollutants, can potentiate the toxicity of the “thioate” type of organophosphorus insecticides.

## PLACENTAL TOXICITY OF METALS

Trace minerals and heavy metals are common contaminants of the environment due to their ubiquitous presence, and thereby pose a serious threat to the environment as well as human and animal health. In excessive concentrations, these minerals and metals are known to adversely affect pregnancy and the development of the conceptus, in addition to the pregnant mother. Placental toxicity of some important metals is described here in brief. It should be noted that much of the pertinent literature mentioned here is from laboratory animals.

### Aluminum

Aluminum (Al) is poorly absorbed following either oral or inhalation exposure, and practically none following dermal exposure. Al can also be absorbed following parenteral routes. It is distributed to many organs, including the liver, lungs, bone, kidney, spleen, heart, brain and muscles. Al also transplacentally traverses and accumulates in the fetal tissues in amounts that adversely influence fetal development. Studies conducted in mice and rabbits revealed that the placenta contained 4–5 times greater Al levels than the fetal or maternal tissues (Yokel and McNamara, 1985; Cranmer *et al.*, 1986). However, the placenta of the guinea pig does not accumulate this metal. It is important to mention that the placental accumulation of Al in mice and rabbits does not preclude its accumulation in the fetal tissues. For further details on toxicokinetics of Al, refer to Yokel (1997), Domingo (2011) and the chapter on Al in this book.

Pregnancy in general enhances susceptibility to Al toxicity. Oral administration of Al is known to cause a developmental syndrome, which includes *in utero* death, delayed ossification of skeleton, malformations and growth retardation, at doses that also influence maternal weight gain. An increased incidence of resorptions occurred in female BALB/c mice treated with 41 mg/kg/day as Al chloride by gavage on GD 7–16 (Cranmer *et al.*, 1986). Gestational exposure of mice to Al lactate (83 mg/kg/day) caused increased incidences of cleft palate, dorsal hyperkyphosis and delayed parietal ossification. Skeletal changes, such as delayed ossification and hypoplastic deformed ribs, were induced in rats exposed to 38–77 mg Al/kg/day by gavage on GD 6–14 (Patermain *et al.*, 1988). The severity of the effects is highly dependent on the form of Al administered. Studies using high Al exposures by iv or ip administration report a developmental toxicity syndrome consisting of death and resorptions, skeletal and soft tissue abnormalities, low birth weights, and growth retardation in rats, mice and rabbits (Wide, 1984; Yokel, 1997). The high incidence of resorptions was markedly greater in pregnant rats treated with Al chloride at dose levels of 75 mg/kg on GD 9–13, 100 mg/kg on GD 14–18 and 200 mg/kg on GD 9–13 (Benett *et al.*, 1975). A high incidence of dead offspring was recovered from mothers treated with Al chloride at a dose level of 200 mg/kg on GD 9–13. These studies indicate that Al can cause delays in skeletal development in pups. Gross fetal abnormalities include abnormal digits, wavy ribs, missing ribs, absence of xiphoid and poor ossification (particularly in the cranial bones, lower part of the vertebral column and the long bones of the limbs). The high incidence of skeletal defects and poor ossification in fetuses of mothers treated with Al chloride suggests that Al has an

adverse influence on fetal bone formation. This is due to the fact that Al binds with phosphate, thereby reducing the amount of phosphate available for bone formation. Depletion of phosphate can also result in fetal internal hemorrhage, due to failure of the blood clotting mechanism. Interestingly, neurotoxicity and neurobehavioral changes have been noted in offspring following Al exposure of rats, mice and rabbits at doses of Al that did not produce maternal toxicity (Yokel, 1997; Bondy, 2010; Domingo, 2011). Other forms of Al, such as Al citrate and Al nitrate, can also produce similar developmental effects. Overall, developing conceptuses are more sensitive than adults to Al toxicity.

## Arsenic

Arsenic (As) occurs in many forms and is commonly found in high concentrations in water and food. Both animal and human studies have shown that As crosses the placenta. Inorganic As crosses the placental barrier and selectively accumulates in the neuroepithelium of the developing animal embryo. Uptake, distribution and metabolism of sodium arsenite (2.5 µg/kg, po) and sodium arsenate (40 µg/kg, po) were determined in pregnant mice on GD 18 (Hood *et al.*, 1987). Maximum concentrations of As in the placenta were found at 4 and 2h after administration of arsenite and arsenate, respectively. Corresponding concentrations in the fetal tissues appeared at 24 and 6h. In the fetal tissues, inorganic As can be converted to the organic form. As is completely eliminated from the placental/fetal tissues within 24h of exposure. Unlike inorganic As, organic As does not cross the placenta, instead it is stored in the placenta. In other studies conducted on hamsters, rats and mice, As ingested at higher doses has been found to be fetotoxic and teratogenic. There is evidence that sodium arsenate and sodium arsenite are embryotoxic (Chaineau *et al.*, 1990). Common deformities include hypoplasia of the prosencephalon, somite abnormalities and failure of development of limb buds and sensory placodes. In hamsters, a single iv injection of sodium arsenate (20 mg/kg) given on GD 8 resulted in 49% malformed and 84% either malformed or resorbed embryos on GD 13 (Holmberg and Ferm, 1969). Common malformations included exencephaly, encephalocele, cleft lip/palate, micro/anophthalmia and ear malformations. In rats, the spectrum of malformations induced by As is similar to that described for hamsters. Placental/fetal toxic effects of As have been more extensively described in mice than rats and hamsters. Exposure of female mice with arsenite/arsenate on GD 9 produces the highest incidence of malformed live fetuses, whereas exposure on GD 11 or 12 produces the highest rate of resorptions. The common external malformations include exencephaly, micrognathia,

exophthalmia, anophthalmia, cleft lip, hydrocephalus, micromelia, ectrodactyly, open eyes, rib defects and vertebral defects. Rats treated with a single gavage dose of 23 mg As/kg as As trioxide on day 9 of gestation had a significant increase in post-implantation loss and a decrease in viable fetuses per litter, while those treated with 15 mg/kg showed no effects (Stump *et al.*, 1999). Rats and mice are much more sensitive than hamsters to organoarsenicals, in terms of placental toxicity. But the most sensitive species is the rabbit, in which 1.5 mg As/kg/day can increase resorptions and decrease viable fetus.

Although the exact mechanism involved in placental toxicity of As is not yet explained, As is known to interact with protein sulfhydryl groups, thereby adversely affecting the activity of many enzymes, including glutamic-oxaloacetic transaminase, pyruvate oxidase, monoamine oxidase, choline oxidase, glucose oxidase, urease, oxidoreductases and kinases. As has also been shown to adversely affect a number of enzymes that are involved in mitochondrial respiration (Rogers, 1996). As inhibits succinic dehydrogenase activity and thereby uncouples oxidative phosphorylation and causes fall of ATP levels affecting virtually all cellular functions (Na<sup>+</sup>/K<sup>+</sup> balance, protein synthesis, etc.). As also exerts its toxic effects to the developing fetus by inhibiting enzymes like thioredoxine reductase, methyltransferases and enzymes of the DNA repair mechanism, disturbing the homeostasis of neurotransmitters and hormones. In addition, As causes oxidative stress. Since As is known to affect vasculature and altered placental and/or embryonal vasculature has been suggested as a mechanism leading to neural tube defects, the embryo may be sensitive to this manifestation of As toxicity. At high dose, As impairs assembly and disassembly of microtubules, thus interfering with mitotic spindle formation and embryonal cell division. As compounds also cause chromosomal aberrations, which may disrupt cell cycling. The direct toxic effects of high levels of As in the developing embryo result not from a difference in the mechanism of toxicity during development, but rather from the existence of a unique target tissue, the neuroepithelium (ATSDR, 2005). Induction of stress proteins or heat shock proteins synthesis in the embryo has been explained as a common mechanism of teratogenesis. Animal studies have also presented evidence that inorganic As may be a transplacental carcinogen.

In essence, inorganic arsenicals are much more toxic than organic arsenicals. Trivalent As is developmentally more toxic than pentavalent As. In fact, pentavalent As compounds exert their toxic actions only after their conversion to the trivalent form. Placental/fetal toxicity of As is of serious concern, especially at the levels that are maternotoxic. For further details on placental, reproductive and developmental toxicity of AS, refer to a recent publication by Flora *et al.* (2011).

## Cadmium

Cadmium (Cd) is a naturally occurring metal found in the earth's crust. Most of the Cd is produced as a byproduct during the production of other metals, such as copper, lead and zinc. The major source of Cd exposure to animals can be from industrial pollution and environmental contamination, especially water. Much of the information obtained on developmental toxicity of Cd is from laboratory animals. By now, it is well established that the placenta itself is a target organ for Cd toxicity. In low to moderate doses, Cd is sufficiently sequestered in the placenta, whereas in high doses, Cd accumulates in the placenta, which perturbs the placental transport of essential elements (such as calcium and zinc), and causes placental necrosis and fetal toxicity. Maternal exposure to Cd is known to cause ultrastructural changes in the placenta, especially trophoblast cell layer II. Common changes include lysosomal vesiculation, nuclear chromatin clumping, nucleolar alterations and mitochondrial calcification. Cd-induced placental necrosis occurs initially in trophoblast cell layer II, which follows rapidly in the remaining trophoblasts. Subcutaneous administration of Cd chloride, Cd acetate or Cd lactate to pregnant rats at a dosage of 0.04 mmol/kg between the 17th and 21st day of gestation resulted in rapid, progressive placental damage, especially in the pars fetalis (Parizek, 1964). Cd-induced necrotic changes could occur as early as within 6 h.

The placenta serves as a remarkable barrier to Cd, and thereby it minimizes fetal toxicity. Cd is known to induce the synthesis of metallothionein (MT), which is a small protein rich in sulfur-containing amino acids and commonly synthesized in maternal tissues and the placenta. MTs retain Cd in maternal tissues and the placenta, and thereby reduce Cd transport to the conceptus. The mechanism involved in developmental toxicity of Cd can be explained based on the interaction between Cd and Zn. In brief, Cd substitutes for Zn in metalloenzymes, thereby Cd interferes with Zn transfer across the placenta. Because of the high affinity of MT for Zn, MT sequesters Zn in the placenta, impeding transfer to the conceptus. Reduced uteroplacental blood flow, reduced nutrient transport and placental toxicity by Cd seem to be the major contributing factors for low fetal birth weight, fetal toxicity, malformations and death. Cd-induced impaired fetal growth is partly due to Zn deprivation, since maternal tissue and the placenta retain Zn. In addition, Cd accumulates in the fetus and produces a variety of adverse effects directly on the fetus. These adverse effects include: (1) embryotoxicity; (2) inhibition of embryonic DNA and protein synthesis; and (3) reduced calcium handling ability of trophoblasts, which is a consequence of alterations in subcellular cytosolic calcium-binding properties. Oxidative stress

and apoptosis are also suggested as mechanisms of cell damage and death.

Maternal exposure to Cd during pregnancy can result in a variety of adverse reproductive outcomes, such as maternal toxicity, placental damage/hemorrhage, impaired implantation, increased resorptions, reduced litter size, fetal growth retardation, congenital malformation in the fetuses and embryonic/fetal death. Exposure to Cd during mid- to late gestation can result in both placental toxicity (reduced blood flow and necrosis) and diminished nutrient transport across the placenta. Exposure during the late gestation can also result in fetal death, despite low levels of Cd entering the fetus (Levin and Miller, 1980; Rogers, 1996).

Cd has also been shown to induce teratogenesis in rats, mice and hamsters. Cd sulfate administered to pregnant hamsters (2 mg/kg, iv) caused high incidence of resorptions. Live fetuses usually show a high rate of malformations, including facial clefts, exencephaly, anophthalmia, limb defects and rib fusions. In rats and mice, the common malformations are club foot, dysplasia of facial bones and rear limbs, cleft palate, micrognathia, sirenomelia/amelia, delayed ossification of the sternum and ribs, microphthalmia/anophthalmia, cryptorchism, gastroschisis and palatoschisis. For further details on placental, reproductive and developmental toxicity of Cd, refer to Flora *et al.* (2011).

## Lead

The common sources of lead (Pb) exposure include Pb-based paints, batteries, crank-case oil, ceramics, shots and sinkers, calking and roofing materials, and ammunition. Plants and animals appear to bioconcentrate lead, but lead is not biomagnified in the aquatic or terrestrial food chain. Pb exposure in pregnant animals usually occurs through the oral route. It is also known that absorption of Pb increases during pregnancy. After oral absorption, Pb is distributed to most of the tissues, but it deposits mainly in the skeleton, kidney and brain (primarily gray matter). Pb is known to cross the placenta and it accumulates in the fetus. Accumulation of Pb occurs in the fetal brain owing to lack of blood-brain barrier. Lead also accumulates in the placenta in times of fetal stress. In fact, a large maternal/fetal concentration gradient exists and the placenta poses a limited transplacental barrier. In addition, a number of adverse maternal health conditions can affect the transfer of lead to the fetus and/or the retention of Pb by the mother or the fetus.

Toxicity of Pb is largely due to its capacity to mimic calcium (Ca) and substitute it in many of the fundamental cellular processes that are Ca dependent. Lead toxicity is induced by interfering with protein/hemoprotein biosynthesis and by inhibiting membrane and

mitochondrial enzymes (Eisenmann and Miller, 1996). Pb is also known to cause deficits in cholinergic, dopaminergic and glutamatergic functions. Recent evidence suggests that oxidative stress is one of the mechanisms involved in lead pathogenesis. Following *in utero* exposure, Pb can have direct effects on the developing conceptus. In fact, the developing nervous system is the most sensitive target of lead toxicity. Developmental toxic effects of Pb have been determined in experimental animals, including rats, mice, hamsters and chicks. *In utero* exposure to Pb can cause reduction in fertility and growth retardation. Embryotoxic and fetotoxic effects of Pb seem to be dependent on the exposure on GD 9; teratogenic effects are observed with few resorptions, compared with exposure on GD 16, with hydrocephalus and CNS hemorrhage (McClain and Becker, 1975). At maternotoxic doses, Pb can cause retarded skeletal development. In mice, Pb can cause postimplantation mortality and skeletal malformations in fetuses. The common skeletal anomaly observed is the fusion of two or more cervical vertebrae (Jacquet and Gerber, 1979). Malformations in hamsters due to Pb exposure occur in the tail, ranging from stunting to complete absence of the tail (Ferm and Carpenter, 1967). In experimental animals, common malformations include brain defects, neural tube defects, and urogenital system and tail defects. It is important to mention that Pb has a greater potential for developmental neurotoxicity than for placental toxicity. For further details on placental, reproductive and developmental toxicity of Pb, refer to Flora *et al.* (2011).

## Mercury

Mercury (Hg) occurs naturally in the environment and exists in several forms. Common sources of Hg include mining, industrial, adhesives, fungicides and interior/exterior paints.

As a result, Hg is a widespread environmental contaminant that threatens the health of animals in general, and aquatic life and wildlife in particular. It is noteworthy that Hg is toxic in all forms. In most food-stuffs, Hg is found in the inorganic form. Fish, marine animals and some microorganisms have capability to convert elemental Hg to organic Hg, which accumulates in the food chain. In most of the poisoning incidents, MeHg was involved because of its popular use as a fungicide. During the outbreak of MeHg poisoning in Japan and Iraq, it was proven that there was transfer of MeHg through the placenta into the fetus. Following *in utero* exposure to MeHg, the target organ is the fetal brain. This is partly due to accumulation of Hg in the fetal brain because of its high requirement for protein synthesis. MeHg is readily absorbed and distributed throughout the body with various concentrations in

different tissues. In humans, brain MeHg levels can be as high as six-fold, compared with blood levels. This is in contrast to rats, which have a brain to blood ratio of 0.06, and mice with a ratio of 1.20. There is evidence that the placenta presents some barrier to Hg. By using the Gray PBPK model for MeHg, the placenta is modeled as four compartments with separate transfer constants for placental barrier and placental tissue transport. Generally, organic and metallic Hg crosses the placenta more readily than inorganic Hg. As a result, MeHg and metallic Hg accumulate in the fetus, whereas inorganic Hg concentrates in the placenta. Metallic Hg, after crossing the placenta, can be oxidized to  $\text{Hg}^{2+}$  in fetal tissues.  $\text{Hg}^{2+}$  accumulates in the placenta, where it inhibits the fetal uptake of certain essential metabolites or analogs of these metabolites.

MeHg has been found to produce embryotoxicity, fetotoxicity and teratogenicity in rats, mice, cats, guinea pigs and hamsters. In general, resorptions, dead fetuses and cleft palate are the most common findings. Some other common developmental effects include generalized edema, brain lesions, wavy ribs, asymmetric sternbrae and decreased ossification of parietal and occipital bones (Domingo, 1994). In essence, prenatal exposure to sufficient amounts of Hg results in developmental toxicity. In addition, Hg has a strong potential for neurotoxicity and neurobehavioral toxicity. For further details on placental, reproductive and developmental toxicity of Hg, refer to Ni *et al.* (2011) and the chapter on mercury in this book.

## PLACENTAL TOXICITY OF INSECTICIDES

Depending upon the duration, frequency and level of exposure, the insecticides of various classes (organophosphates, carbamates, organochlorines and pyrethroids) can adversely affect one or all three components of the maternal/placental/fetal unit. Numerous studies demonstrate that the insecticide residue is present in the exposed mother, placenta, cord blood, embryo and fetus, suggesting that the placenta and fetus are potentially exposed to these compounds. In this chapter, organophosphates (OPs) and carbamates (CMs) are discussed together because their mechanism of action and effects are quite similar (Gupta, 1995; Pelkonen *et al.*, 2006; Gupta, 2009; Gupta, 2011a; Gupta *et al.*, 2011).

### Organophosphates and carbamates

In general, both OPs and CMs exert their overt toxicity by inhibiting the activity of acetylcholinesterase (AChE).

Inactivation of AChE occurs owing to phosphorylation by OPs and carbamylation by CMs. Inhibition of AChE results in accumulation of acetylcholine (ACh), which overstimulates the muscarinic and nicotinic ACh receptors. There is evidence from a rat study that placenta may be a target of direct toxic effect by organophosphate pesticides (Levario-Carrillo *et al.*, 2004). By having active metabolic activity, the placenta can modulate the potency of OPs and CMs. The placenta can probably convert certain OPs of the "thioate" or "dithioate" group to their "oxon" analogs, which are many times more potent AChE inhibitors and thus more toxic than their parent compounds. In such circumstances, the placenta can be one of the several determining factors for fetal toxicity.

It is well established that an active cholinergic system exists in the placenta of some species and not in others, and there is evidence that a cholinergic system may have more than one function in placenta. In the placenta, ACh-like activity is highest in membranes, medium in the cotyledons and minimal in the cord, and it varies in the placenta as a function of gestational stage. The concentration of ACh in the placenta (a non-innervated tissue) is found to be greater than in various regions of the brain, and a marked decline occurs soon after parturition and expulsion of the placenta. The existence of the cholinergic system (using choline acetyltransferase activity, ChAT) has been studied in the term placenta of several species (monkey, mongoose, lemur, horse, cow, sheep, goat, pig, hamster, cat, rabbit, guinea pig and rat) (Hebb and Ratkovic, 1962). Literature abounds showing that the two species in which the placental cholinergic system has definitely been found are the two higher primates, man and monkey. In general, ACh has many functions in the placenta: (1) it acts as a local hormone related to uterine contractions and mechanisms associated with birth; (2) it controls permeability and transport; (3) it regulates blood flow and fluid volume in placental vessels; (4) it is involved in the mechanism of parturition; and (5) it acts as a local messenger molecule. ACh also seems to play a vital role in the maturation of the placenta. In addition, ACh may regulate trophoblastic channels, fluid balance and osmotic pressure, and therefore may influence contractile properties of myofibroblasts in the placenta. For further details on the roles of ACh, refer to Sastry (2000).

The placenta and fetus, by having AChE and other cholinergic elements (muscarinic and nicotinic ACh receptors), remain susceptible to OPs and CMs. Inhibition of AChE and BuChE activities can be used as a marker of exposure to an OP or CM, while AChE can also be used as a marker of effects. OPs and CMs readily cross the placental barrier and can act on the cholinergic and non-cholinergic components of the developing nervous system and other vital organs (Gupta *et al.*, 1984,

1985; Pelkonen *et al.*, 2006; Gupta, 2009). Significant inhibition of AChE and/or BuChE activities in maternal, placental and fetal tissues of rats and mice following prenatal exposure to several OPs (quinalphos, dicrotophos, methyl parathion, diazinon, etc.) has been demonstrated (Bus and Gibson, 1974; Srivastava *et al.*, 1992; Gupta, 1995; Abu-Qare and Abou-Donia, 2001; Gupta, 2009; Gupta *et al.*, 2011). Similar findings have been reported for CMs, including aldicarb, carbaryl, carbofuran and pirimicarb (Declume and Derache, 1977; Cambon *et al.*, 1979, 1980). From all these studies, AChE inhibition appears to be the major mechanism of toxicity. With either type of insecticides, the developing organism is much more sensitive to the induction of functional neural deficits. Furthermore, subchronic prenatal exposure to methyl parathion in rats resulted in altered postnatal development of brain AChE and ChAT activities, in addition to selected subtle alterations in behavior (Gupta *et al.*, 1985).

Anticholinesterase compounds have strong potential for embryotoxicity, embryoletality, fetotoxicity and teratogenesis. These effects vary depending upon the particular OP and CM involved. With these compounds, embryoletality is encountered so often that the expression of teratogenesis is rarely seen. In some experimental studies conducted in rats, mice, rabbits and hamsters, OPs at maternotoxic doses have been shown to produce developmental alterations, including growth retardation and embryotoxicity. Khera (1979) discovered polydactyly in fetuses of cats treated with dimethoate (12 mg/kg/day) during the 14th to 22nd day of pregnancy (Figure 20.1).

Methamidophos administration at a no-maternal toxicity dose (1 mg/kg, po) to female rats during GD 6–15 produced neither lethal effect on embryos nor caused congenital malformations at term; however, the embryo/fetal maturation process was significantly altered (De Castro *et al.*, 2000).

Wide species variability exists in sensitivity to OP-induced placental toxicity. It needs to be mentioned that the mechanisms involved in embryonic/fetal developmental malformation appear to be different from those involved in general toxicity. Alkylation of nicotinamide adenine dinucleotide (NAD<sup>+</sup>) coenzymes by OPs is the major mechanism involved in the induction of teratogenesis (Schoental, 1977). In recent studies, DFP and carbofuran have been shown to cause marked depletion of NAD<sup>+</sup> in rats (Gupta *et al.*, 2001a, b). OPs are also known to cause alterations in the levels of RNA, glycogen, sulfated mucopolysaccharides and calcium in the developing tibiotarsus bones. Prenatal exposure to OPs has been shown to affect protein synthesis both *in vivo* (Gupta *et al.*, 1984) and *in vitro* (Welsch and Dettbarn, 1971; Marinovich *et al.*, 1996). The inhibitory effect on *in vivo* protein synthesis of methyl parathion (daily oral exposure throughout the period of organogenesis) was

**FIGURE 20.1** Fetal cat showing heptadactyly (right forepaw) and hexadactyly (left forepaw), from a cat exposed to dimethoate (Khera, 1979).

**FIGURE 20.2** Methyl parathion-induced inhibition of *in vivo* protein synthesis in placental, fetal and maternal tissues. An asterisk indicates a significant difference between methyl parathion-treated and control rats.

shown to be dose dependent, greater on day 19 than day 15 of gestation and more pronounced in fetal than in placental or maternal tissues of rats (Gupta *et al.*, 1984). The inhibitory effect on protein synthesis was more pronounced at a dose causing overt maternal toxicity (Figure 20.2). A mixture of OPs, including diazinon, dimethoate and azinphos, has been found to be more toxic to protein synthesis than any of the single OP compound alone (Marinovitch *et al.*, 1996).

Many placental toxicity studies conducted in mice, rats, hamsters and rabbits revealed no teratogenic responses to OPs. Among CMs, carbaryl is the only insecticide that has been studied in detail for placental toxicity. Like OPs, CMs have a greater potential for embryoletality and fetotoxicity and that precludes an expression of teratogenicity. Beagle dogs receiving carbaryl gave birth to fetuses with terata in 21 of a total of 181 pups. Fetal abnormalities included abdominal/thoracic fissures with varying degrees of intestinal agenesis and displacement, brachygnathia, ecaudate pups, failure of skeletal formation and superfluous phalanges (Smalley *et al.*, 1968). Carbaryl exposure during organogenesis produces terata in guinea pigs, but not in hamsters and rabbits. Other carbamates, such as carbofuran and propoxur, have not been found to be teratogenic. For further details on placental, reproductive and developmental toxicity of OPs and CMs refer to Gupta *et al.* (2011).

## Organochlorines

Organochlorine insecticides are classified into three groups: (1) dichlorodiphenylethanes (dichlorodiphenyl-trichloroethane, dicofol, methoxychlor and perthane); (2) hexachlorocyclohexanes (benzene hexachloride, chlordane, lindane, mirex and toxaphene); and (3) chlorinated cyclodienes (aldrin, dieldrin, endrin, chlordane, endosulfan and heptachlor).

The mechanism of action of organochlorines is not yet fully explained. The dichlorodiphenylethane (DDT type) compounds alter the transport of sodium and potassium ions across axonal membranes, resulting in an increased negative after-potential and followed by prolonged action potentials. As a result, repetitive firing and a spontaneous train of action potentials occur. Specifically, DDT inhibits the activation of sodium channels and the activation of potassium conductance. The mechanism involved in cyclodiene-induced hyperactivity of the CNS and convulsions can be explained based on their structural resemblance to the cyclic  $\gamma$ -aminobutyric acid (GABA) receptor antagonist picrotoxin. The mammalian GABA receptor is coupled to an intrinsic chloride ion channel and is the primary mediator of neuronal inhibition in the brain. Like picrotoxin, cyclodienes block the inhibitory action of GABA. Similar to other organochlorines, mirex and kepone cause stimulation of the CNS, hepatotoxicity and induction of the mixed-function oxidase system. In the CNS, symptoms observed in animals by cyclodiene organochlorines include tremors, convulsions, ataxia and changes in EEG patterns. The CNS symptoms could be due either to (1) inhibition of the  $\text{Na}^+/\text{K}^+$ -ATPase or the  $\text{Ca}^{2+}/\text{Mg}^{2+}$ -ATPase activity, which can then interfere with nerve action or release of neurotransmitters, and/or (2) inhibition of the GABA receptor function.

The acute toxic signs associated with DDT and chlorinated benzene types of insecticides include paresthesia of the tongue, lips and face, apprehension, tremors and convulsions. Stimulation of the CNS is the most prominent effect. The acute signs and symptoms produced by cyclodienes include dizziness, nausea, vomiting, myoclonic jerking, motor hyperexcitability and seizures. Usually, epoxide metabolites of cyclodiene type of insecticides are much more toxic than their parent compounds. It is important to mention that the developing nervous system is the most sensitive target of organochlorine toxicity.

Only a few placental toxicity studies have been conducted with organochlorine compounds. In experimental studies, organochlorines, including DDT, DDE, DDD, dieldrin, endosulfan, methoxychlor and toxaphene, have been associated with estrogen-like effects in the reproductive system of laboratory animals. Exposure of female rats to methoxychlor before and during pregnancy can cause blockade of implantation, suppression of uterine decidualization, lack of corpora lutea and atresia of ovarian follicles. Exposure during preimplantation blocks implantation, whereas exposure during postimplantation causes fetal resorptions. Interference in the requisite hormonal milieu seems to be the major effect. Other effects of methoxychlor include estrogenic effect on uterine preimplantation differentiation, ovum transport rate, luteal regression and postimplantation decidual growth. In an experimental study, exposure of Swiss mice to lindane at different stages of pregnancy produced various toxicological effects, such as fetotoxicity and reproductive failure (Sircar and Lahiri, 1989). Lindane exposure during early pregnancy (days 1–4) caused total absence of any implantation; during mid-pregnancy (days 6–12) caused total resorptions of fetuses; and during late pregnancy (days 14–19) caused the death of all pups within 12 h to 5 days after parturition. Lindane can also cause reproductive failure by inducing a deficiency of steroid hormones (estrogen and progesterone).

Some studies in animals suggest that young animals exposed during gestation and infancy may be very sensitive to heptachlor and heptachlor epoxide. Changes in nervous system and immune function were found in these animals. Exposure to higher doses of heptachlor in animals can also result in decreases in body weight and death in animal newborn babies. A decrease in fertility and an increase in resorptions were observed in female rats acutely exposed to 1.8 mg/kg/day. Reduced fertility has also been observed in mice exposed to 8.4 mg/kg/day. A number of animal studies have demonstrated that exposure to heptachlor can result in decreased fertility and pregnancy losses. Impaired fertility was reported in female rats administered via gavage of 0.6 mg/kg/day heptachlor in groundnut oil for 14 days prior to mating (Amita Rani and Krishnakumari, 1995). In essence, though the exact mechanism in the

placental toxicity is yet to be elucidated, impaired fertility and pregnancy losses, in addition to the impaired development of the nervous system and immune system, have been found with organochlorines.

There are reports that dieldrin produced teratogenic effects, such as supernumerary ribs, with concomitant decrease in ossification centers in fetal hamsters (Chernoff *et al.*, 1975, 1979). In rats, exposure to mirex during pregnancy has been associated with perinatal deaths due to persistent cardiovascular problems, such as first- to third-degree fetal heart blockade (Grabowski, 1983). In addition, mirex causes altered lens growth and cataracts, along with other biochemical, physiological and histological changes (Rogers and Grabowski, 1983). Further details on reproductive and developmental toxicity of organochlorines can be found in a recent publication elsewhere (Malik *et al.*, 2011).

## Pyrethrins and pyrethroids

In recent years, the use of synthetic pyrethroids over other classes of insecticides has increased tremendously because of their selectively high toxicity to insects and low toxicity to mammals. Still, the risks to animal health exist because the products containing pyrethrins and pyrethroids are commonly used as ectoparasiticides. Exceeding the recommended levels of these insecticides or time of exposure often results in poisoning and deaths, especially in cats and dogs. Pyrethroids are of two types. Type I pyrethroids are those that lack  $\alpha$ -cyano moiety and give rise to the tremor syndrome (T syndrome). The syndrome includes the signs of whole body tremors, incoordination, prostration, tonic/clonic convulsions and death. A few common examples of type I are pyrethrin I, allethrin, tetramethrin, resmethrin and permethrin. Type II pyrethroids are those which contain  $\alpha$ -cyano moiety and cause the choreoathetosis/salivation (CS) syndrome. The CS syndrome is characterized by hyperactive behavior, profuse salivation, tremors, motor incoordination and hunch-backed posture. A few common examples of type II pyrethroids include cyphenothrin, cypermethrin, deltamethrin and fenvalerate.

Intoxication by pyrethroids results primarily from hyperexcitation of the nervous system. Type II syndrome involves primarily an action in the CNS, whereas with type I syndrome, peripheral nerves are also involved. Hyperexcitation of the nervous system is caused by repetitive firing and depolarization in nerve axons and synapses. Pyrethroids act directly through interaction with the sodium channel gating mechanism, thereby interfering with the generation and conduction of nerve impulses and inducing marked repetitive activity in various parts of the brain. Type I pyrethroids affect sodium channels in nerve membranes, causing repetitive

neuronal discharge and a prolonged negative after-potential, the effect being similar to those produced by DDT-type insecticides. Type II pyrethroids produce an even longer delay in sodium channel inactivation, leading to a persistent depolarization of the nerve membrane without repetitive discharge, a reduction in the amplitude of the action potential and eventually failure of axonal conduction and a blockade of impulses.

Prenatal or early postnatal exposure to pyrethroids (cypermethrin, fenvalerate and others) has been linked with significant neurochemical alterations in neonatal rats (Husain *et al.*, 1991; Malaviya *et al.*, 1993). Delayed maturation of the cerebral cortex occurs due to alterations in key enzymes of the neurotransmission process (e.g., monoamine oxidase, acetylcholinesterase and Na<sup>+</sup>/K<sup>+</sup>-ATPase). Prenatal exposure to these insecticides significantly delays differential responses in the levels of brain regional polyamines and ontogeny of sensory and motor reflexes in offspring. Other biochemical and neurochemical effects of these insecticides include impairment at the neurotransmitter receptors, including dopaminergic, cholinergic and catecholaminergic.

Compared to other classes of insecticides, pyrethroids are not well studied for placental toxicity because they are relatively less toxic to mammalian species. For example, permethrin at concentrations of 2000–4000 ppm showed only a week to moderate influence on *in utero* fetal development. Zhang *et al.* (2008) revealed that *cis* isomer of permethrin induced reproductive toxicity and not *trans* isomer. Female rats dermally exposed to cyhalothrin throughout the gestation period had offspring with delayed fur development, delayed ear and eye opening and delayed descent of the testes, but with no change in the age of vaginal opening. In adulthood, however, the sexual behavior of both male and female rats exposed to cyhalothrin prenatally is no different from that of control animals (Gomes *et al.*, 1991a, b). Prenatal exposure of rats to deltamethrin caused increase in early embryonic deaths and fetuses with retarded growth, hyperplasia of the lungs, dilatation of the renal pelvis and increase in placental weight (Abdel-Khalik *et al.*, 1993).

## Mycotoxins

Mycotoxins are secondary metabolites of fungi and several of them are found to be toxic *in utero* in both man and animals. In general, mycotoxins can produce placental toxicity by one or more of three common mechanisms. In brief, mycotoxins can interfere with hormonal activity, which can damage parental gametes, producing infertility or abnormal offspring if successful fertilization occurs. Mycotoxins can cause fetal malformations, especially during organogenesis, by interfering with fetal nucleic acid and protein biosynthesis. This interrupts normal

cell differentiation and organogenesis, resulting in fetal malformations. Mycotoxins can also affect the fetus indirectly by affecting vital maternal organs, such as the liver, reducing nutrient transfer to the fetus or increasing transfer of toxicants. Some of the common mycotoxins that cause placental toxicity are briefly discussed below.

## Aflatoxins

Aflatoxins (B<sub>1</sub>, B<sub>2</sub>, G<sub>1</sub> and G<sub>2</sub>) are mainly produced by *Aspergillus flavus* and *Aspergillus parasiticus*, which commonly contaminate a variety of animal food. Aflatoxins are proven to be mutagens, carcinogens and teratogens. Some of the aflatoxins and their metabolites are known to cross the placental barrier in humans as well as in animals. From limited studies conducted on laboratory animals, aflatoxin B<sub>1</sub> and G<sub>1</sub> appear to have strong potential for embryocidal, fetotoxic and teratogenic effects. Aflatoxin B<sub>1</sub> and G<sub>1</sub>, with varying doses administered orally or ip in mice on gestation day (GD) 12 and 13, produced moderate retardation in fetal development, cleft palate and changes in diaphragm. Aflatoxin G<sub>1</sub> also produced malformations in the kidneys (Roll *et al.*, 1990). Pregnant rats exposed to aflatoxin B<sub>1</sub> via the oral route have been shown to result in significant anti-implantational activity and loss of viability among the litters (Choudhary *et al.*, 1992). For the reproductive and developmental effects of aflatoxins refer to a recent publication elsewhere (Gupta, 2011b).

## Fumonisin

Fumonisin (FB<sub>1</sub>, FB<sub>2</sub>, FB<sub>3</sub>, FB<sub>4</sub>, FA<sub>1</sub>, FA<sub>2</sub>, C<sub>1</sub> and several others) are produced by *Fusarium* fungi, primarily *F. verticillioides* (formerly *F. moniliforme* Sheldon) and *F. proliferatum*. These mycotoxins are found in corn and therefore contaminate corn-based food/feed worldwide. Over 28 fumonisins have been identified, but FB<sub>1</sub> and FB<sub>2</sub> are the most abundant and most toxic mycotoxins of this group. Fumonisin-induced toxic effects appear to be species specific. Consumption of fumonisin-contaminated food/feed has been associated with many organ-specific diseases. For example, esophageal cancer in man in the Transkei region in South Africa and Linxian County in China, hepatopathy and hepatocarcinoma in laboratory rats, porcine pulmonary edema (PPE) in swine, and equine leukoencephalomalacia (ELEM) or moldy corn poisoning in equidae. In addition, fumonisins produce mild to fatal toxicity in the liver, kidney and heart of rats and horses. Among all species, equidae is the most sensitive because fumonisins affect the brain of this species.

Experimental animal studies and field-case findings revealed that fumonisins have a strong potential for

developmental toxicity and teratogenicity (Voss *et al.*, 2011). Purified FB<sub>1</sub> and *F. proliferatum* culture extract have been shown to be embryotoxic when inoculated into incubated eggs (Javed *et al.*, 1993a, b). In addition to mortality, which was dependent on the dose and time of administration (i.e., day 1 or 10), embryonic changes occurred, including hydrocephalus, enlarged beaks and elongated necks. In hamsters, FB<sub>1</sub> caused increased incidence of prenatal losses, including deaths and resorptions. At a dose of 12 mg/kg, all litters were affected and all the fetuses were dead and resorbed, without any clinicopathological evidence of maternal toxicity. Fetal resorptions were associated with a greater severity of placental necrosis. Placental tissues showed signs of degeneration and involution, focal distortion and necrosis of the trophoblastic layer, especially at the periphery, and hemorrhage and necrosis at the base of the placenta. Placentas had extensive necrosis and fetal capillaries in the hemochorial portion, with concomitant collapse of the stroma. Such changes were consistent with the embryo-lethal effects of FB<sub>1</sub>. External malformations include hooked or curled tail, ectrodactyly of the front/rear limbs and cleft palate. Developmental effects of aqueous culture extract of *F. moniliforme* in CD1 mice are reported to be due to FB<sub>1</sub>. The effects include maternal deaths, reduced maternal body weight gain, increased embryonic resorptions, reduced pup weights and fetal malformations, such as cleft palate, hydrocephalus and ossification deficits (Gross *et al.*, 1994; Reddy *et al.*, 1995).

FB<sub>1</sub> is found to be fetotoxic in F344/N rats. Pregnant rats receiving FB<sub>1</sub> at a dose of 30 or 60 mg/kg, po (GD 8–12) developed significant impairment of ossification of the sternebrae and vertebral bodies in their fetuses (Lebepe-Mazur *et al.*, 1995). It appears that FB<sub>1</sub> produces fetotoxicity in rats by suppressing growth and fetal bone development (Figure 20.3). However, in Sprague-Dawley rats, there is little or no evidence of embryotoxicity or fetotoxicity by FB<sub>1</sub>, especially in the absence of maternal toxicity (Ferguson *et al.*, 1997). Pregnant New Zealand white rabbits receiving FB<sub>1</sub> showed no evidence of embryotoxicity or teratogenicity, despite the fact that the pregnant rabbits were very sensitive to FB<sub>1</sub> (LaBorde *et al.*, 1997).

In pregnant mares, late term abortions have been observed by consuming fumonisin- contaminated corn/corn-based feed. The surviving colts are usually slow learners and behaviorally abnormal. Suppressed growth, bone development and immune system appeared to be the major contributing factors. Abortions have also been observed in pregnant sows by consuming fumonisin-contaminated corn that caused hypoxia resulting from maternal respiratory distress (Harrison *et al.*, 1990).

Although the exact mechanism of action involved in fumonisin toxicity is yet to be established, it has been demonstrated that fumonisins inhibit sphinganine/sphingosine

**FIGURE 20.3** Skeletal development of control- (A) and fumonisin- (B) treated rat pup. A = pup from a control dam, with normally shaped ribs and normal ossification of the phalanges and vertebrae bodies. B = pup from a dam treated with 60 mg/kg fumonisin B<sub>1</sub>, having under-ossification of the vertebral bodies of the cervical and lumbar regions as well as the phalanges (Lebepe-Mazur *et al.*, 1995).

N-acetyl transferase (ceramide synthase) activity, and consequently increase the concentrations of sphinganine to sphingosine in target organs of many species (Wang *et al.*, 1992; Riley *et al.*, 1993). Accumulation of sphinganine may be responsible for cell death because long-chain bases such as sphinganine and sphingosine are known protein kinase C inhibitors and can be cytotoxic. It is suggested that an abnormal sphinganine/sphingosine ratio in the fetus, while normal ratio in the dam, may attest to the unique sensitivity of the conceptus to fumonisins. For further details on placental, reproductive and developmental toxicity of fumonisins, refer to Voss *et al.* (2011) and the chapter on fumonisins in this book.

## Ochratoxin A

Ochratoxin A (OTA) is produced by several *Aspergillus* and *Penicillium* species. This mycotoxin is known to contaminate food/feed and thereby cause a variety of adverse health effects (nephrotoxicity, carcinogenicity, teratogenicity and immunotoxicity), nephrocarcinogenicity being the most prominent. OTA has been demonstrated to cause carcinogenesis, immunotoxicity and teratogenesis in rats and rabbits (Mayura *et al.*, 1982a; Wangikar *et al.*, 2004). In general, the underlying mechanisms involved in the toxicity of OTA include: (1) inhibition of protein synthesis, (2) increased lipid peroxidation and (3) partial inhibition of ATP-dependent calcium uptake and inhibition of the cell-mediated immune

response. In addition, OTA inhibits the phosphorylase enzyme system, possibly by competing with 3',5'-cyclic AMP for phosphorylase b kinase activity. In the kidney, OTA specifically affects organic anion transport, but not organic cation transport, in both the brush border and basolateral membranes, which explains its entry into the renal cells and the development of toxicity. Gene expression study indicates that OTA-induced renal toxicity involves the impairment of defense potential causing oxidative damage that eventually leads to cell proliferation and cancer. Epigenetic mechanism appears to be highly probable (Marin-Kuan *et al.*, 2006)

A recent toxicokinetic study in rats revealed that bioavailability of OTA is significantly greater in adult males than in females and young animals (Vettorazzi *et al.*, 2010). Fasting further enhances the oral absorption of OTA. Following absorption, OTA transplacentally traverses in rodents and other species and causes fetal death in laboratory and domestic animals (Still *et al.*, 1971). Pregnant rats receiving a culture of *A. ochraceus* on GD 10 showed embryo resorptions and fetal deaths. Subsequent studies in rats further demonstrated that a high dose of purified OTA administered on GD 10 also caused a large number of fetal deaths and embryo resorptions. However, in sheep, placental transfer of OTA was found to be in trace amounts resulting in very little or no evidence of fetal toxicity or teratogenesis. Rabbits receiving a combination of OTA and aflatoxin B<sub>1</sub> showed antagonistic interaction, yet revealed a characteristic cardiac anomaly with a valvular defect at the auriculo-ventricular junction (Wangikar *et al.*, 2005). For further details of OTA toxicity in general and reproductive and developmental toxicity in particular, refer to Gupta (2011b) and the chapter on OTA in this book.

## Rubratoxins

Both rubratoxin A and B are produced by *Penicillium rubrum* and *P. perpurogenum*. Rubratoxin B is the primary mycotoxin that causes hepatotoxicity, nephrotoxicity and splenotoxicity in several animal species. In both laboratory and domestic animals, typical signs of poisoning are hepatic failure, coagulopathy, hemorrhage of the gut mucosa, bloody feces and death. Rubratoxin B<sub>1</sub> has been demonstrated to be a potent mutagen and teratogen in laboratory animals (Wilson and Harbison, 1973). Although the underlying mechanism in rubratoxin-induced placental toxicity is yet to be explained, rubratoxin B is known to produce gross malformations, internal anomalies, skeletal malformations, embryo lethality, intrauterine growth retardation, increased skeletal variations and delayed ossification in the mouse fetuses. The teratogenic effects in near-term fetuses include exophthalmos, missing ears, spina bifida,

microphthalmia, anophthalmia, short tail, exencephaly and hydramnion.

## Secalonic acid D

Secalonic acid D (SAD) is produced by *Penicillium oxalicum*. In rats and mice, SAD is known to cause embryotoxicity, embryoletality, fetotoxicity and teratogenicity. Pregnant CD1 mice receiving SAD (>5mg/kg/day, ip, GD 7–15) showed a reduction in maternal body weight gain, and an increase in resorptions of implanted embryos (Reddy *et al.*, 1981). The resorptions rate was found to be 100% at 15mg/kg dose. Multiple gross, skeletal and visceral anomalies were noted in fetuses born to mothers receiving 10mg/kg or more. Major malformations included cleft palate, cleft lip, open eyelids, missing phalangeal ossification centers and shortened mandibles. In CD1 mice, SAD is proved to be an embryocidal, fetotoxic and teratogenic. Pregnant rats receiving SAD as a single sc dose (25mg/kg) on one of GD 6–10, 12 or 14, or 15mg/kg on GD 10, produced fetotoxic and teratogenic effects, although the effects were less marked with the lower dose (Mayura *et al.*, 1982b). The highest number of resorptions, greatest depression of fetal body weight and largest number of malformations occurred when SAD was injected on GD 10. The major gross malformations were anophthalmia (GD 9 and 10), exencephaly (GD 9) and defects in limbs, digits and tail (GD 10). The major skeletal defects involved the vertebrae and ribs. The major internal soft tissue defects were hydronephrosis (GD 9 and 10), tracheo-esophageal fistula and renal agenesis (GD 10). In essence, pregnant rats are most sensitive to SAD exposure on GD 10 for fetotoxicity and teratogenicity.

## Trichothecenes

The trichothecenes are a group of structurally related mycotoxins with varying degrees of cytotoxic potency. Diacetoxyscirpenol (DAS), T-2 toxin and deoxynivalenol (DON or vomitoxin) are the three major mycotoxins of this group that are commonly encountered in animal poisonings. T-2 and DAS are produced by *F. sporotrichioides* and vomitoxin is produced by *F. roseum*. There is strong evidence that trichothecenes cross the placental barrier and can cause both embryonic death and structural malformations when administered to laboratory animals during pregnancy (Francis, 1989). Since domestic and avian species are exposed to trichothecenes through consumption of contaminated feed, and trichothecenes in general cause feed refusal, it is expected that the induced maternal/fetal toxicity be minimal. Furthermore, *in vivo* studies with different animal

species indicate that orally or parenterally administered trichothecenes do not bioaccumulate due to their short elimination half-lives: <30min for T-2 toxin in swine, cattle and dogs (Yagen and Bialer, 1993), and 3–5 h for DON in swine and cattle (Rotter *et al.*, 1996).

## DON

Feeding of a deoxynivalenol (DON, vomitoxin)-contaminated diet at 5ppm to rats throughout gestation does not adversely affect pregnancy or increase birth defects (Morrissey, 1984). Vomitoxin does not produce teratogenesis even at a 20ppm level. However, at this dose it can decrease the rate of pregnancy. Mice intubated with vomitoxin (2.5 and 5mg/kg) on GD 8–11 produced embryoletality, and at doses of 5mg/kg or greater produced embryoletality (Khera *et al.*, 1982). In mice, vomitoxin at a dose of 10mg/kg caused maternal mortality. Fetal mortality by vomitoxin is dose dependent (100% at 10mg/kg, 80% at 5mg/kg and 72% at 2.5mg/kg). However, none of the doses of vomitoxin induced damage to the placenta or teratogenesis in mice.

## DAS

There is very little known about placental toxicity of diacetoxyscirpenol (DAS). In rats, DAS at a dose rate of 2, 3 or 6mg/kg ip given on one of GD 7–11 caused no maternal toxicity (Mayura *et al.*, 1985). The highest dose of DAS caused 100% resorptions, while with the lowest dose, the surviving pups showed a variety of malformations, including hydrocephaly and exencephaly.

## T-2 toxin

T-2 toxin is the most potent mycotoxin of the trichothecenes group, and has been involved in mass poisoning in animals (Hsu *et al.*, 1972). It has been well established that T-2 toxin crosses the placenta (Hayes, 1981). In rats, T-2 toxin produced behavioral teratogenesis, when the toxin was given prenatally (Francis, 1989). Mice exposed to a single dose of T-2 toxin (3mg/kg) on GD 7, 8, 10, 11 or 12, showed maternal toxicity with 17% mortality and whole litter resorptions (Roussoux *et al.*, 1985). Maternal death was typically due to placental hemorrhage, and surviving pups showed retardation defects of the skeletal system, exencephaly, abdominal defects and cleft palate. The findings of a comprehensive study in mice treated with T-2 toxin (0.5, 1.0 or 1.5mg/kg, ip) on GD 7, 9, 10 or 11 are briefly described in Stanford *et al.* (1975). Treatment on GD 9 reduced the survival rate to 85% at 1mg/kg and to 8% at 1.5mg/kg, without any evidence of teratogenesis in surviving pups. Among the

surviving pups of dams treated at 1.0 or 1.5mg/kg on GD 10, 37% grossly malformed and 42% had skeletal malformations. Commonly observed malformations were exencephaly, congenitally open eyelids and retarded jaws. Treatment on GD 11 resulted in greater embryotoxicity (75% deaths at 1mg/kg and 100% deaths at 1.5mg/kg), but the malformation rate among surviving pups was not greater than 13% at any dosage. In another study, mice given T-2 toxin in feed at 5 and 10ppm throughout gestation resulted in whole litter abortions in 67 and 100% of the dams, respectively (Francis, 1989). Delayed ossifications of the coccyx and growth retardation were the prominent effects. Overall, the observed effects were cumulative and dose dependent.

It appears that the trichothecenes induce embryotoxicity at maternotoxic doses in laboratory animals. Death of the embryo/fetus is the most common finding. The surviving pups rarely show frank malformations of nervous system and skeletal system.

For further details on trichothecenes toxicity in general and reproductive and developmental toxicity in particular, refer to Mostrom (2011) and Chapter 94 in this book.

## Zearalenone

Zearalenone is produced by the fungi *Fusarium graminearum*, *F. culmorum* and other *Fusarium* species. It is important to study the placental toxicity of zearalenone and its two major metabolites ( $\alpha$ - and  $\beta$ -zearalenol) as they bind to estrogen receptor and produce a variety of reproductive problems. Zearalenone has been found to cross the placenta and reach fetuses of mice and rats (Appelgren *et al.*, 1982; Bernhoft *et al.*, 2001). In maternal tissues, zearalenone and its metabolites accumulate in the liver, but in fetal tissues it is yet to be established. Due to its estrogenic activity, zearalenone is known to perturb the ovulation cycle and reduce litter size in domestic animals, particularly swine. Similar findings have been noted in experimental studies conducted in swine, mice and rats, while exposure to zearalenone during pregnancy reduces fetal survival (Kuiper-Goodman *et al.*, 1987). The structurally related compound  $\alpha$ -zearalanol, which is used for growth promotion in cattle, has been shown to accelerate testicular development and exert alterations in Leydig cells in mice after *in utero* exposure (Perez-Martinez *et al.*, 1997).

## TOBACCO

Tobacco plants and their products contain many toxic alkaloids, but nicotine is believed to be the major component causing alterations in embryo and fetal development

that leads to teratogenesis. Pets are exposed to tobacco by ingesting commercial products (e.g., cigarettes, chewing tobacco, etc.), whereas livestock are exposed by consuming discarded tobacco stalks or contaminated hay with tobacco plant dripping in the barn. Most often, poisoning encountered in animals with tobacco is acute in nature, exhibiting the signs of neurologic and muscular disturbances.

The pharmacological and toxicological effects of nicotine are dose dependent and primarily occur in the CNS, cardiovascular system, skeletal muscles and GI tract. Nicotine is a rapidly acting sympathetic and parasympathetic ganglionic depolarizer. In small doses, nicotine stimulates the autonomic ganglia, while in larger doses it blocks the ganglia. Similarly, in skeletal muscles small doses of nicotine initially stimulate the nicotinic receptors of the motor end plate, while larger doses block these receptors. Cardiovascular signs, such as tachycardia and hypertension, result from stimulation of sympathetic ganglia and the adrenal medulla. Death occurs from paralysis of respiratory muscles and cardiac arrest.

Some tobacco alkaloids, especially nicotine, have been studied for their distribution, metabolism and elimination in animals. It is also established that some of these alkaloids cross the placenta and produce teratogenic effects (Suzuki *et al.*, 1974; Sastry and Janson, 1995; Panter *et al.*, 1999; Czekaj *et al.*, 2002). In some studies, tobacco components have been shown to produce deleterious effects on embryonic development in the early stages of pregnancy, before the placenta is fully formed. In mice, nicotine increases  $[Ca^{2+}]_i$  and reactive oxygen species levels, which play a role in nicotine-induced embryonic apoptosis and malformations, and that eventually leads to teratogenesis (Zhao and Reece, 2005). Swine appears to be the most sensitive species in the context of teratogenesis. The fetal arthrogryposis occurs without signs of intoxication in the dams and without fetal deaths or abortions, but the deformed piglets usually die shortly after birth. With *N. glauca* fetal deformities are preceded by the appearance of signs of acute toxicity in the dam (Keeler *et al.*, 1981). Deformities in the newborn following *in utero* exposure include severe flexure and lateral rotation of the carpal joints, moderate rotation of the fetlocks and less commonly spinal malformations resulting in lordosis or scoliosis, and cleft palate (Burrows and Tyrl, 2001). Exactly, which component(s) of the tobacco is involved in inducing teratogenesis is yet to be confirmed.

## CONCLUSIONS AND FUTURE DIRECTIONS

Until recently, placental toxicity has received very little attention compared to fetal or maternal toxicity. This is

due to the fact that placenta is discarded at the termination of pregnancy. However, healthy placenta with normal structure and function is required for proper supplies of nutrition to the fetus and its protection from adverse conditions. It is important to mention that the placenta is also a source of several growth factors that are required by the fetus. The placenta by having an active metabolism appears to influence fetal toxicity of chemicals. Many chemicals cross the placenta and produce deleterious effects on the fetus, while other chemicals cause damage to the placenta and thereby adversely affect the fetus. Detailed studies need to be done to understand exactly how the toxicants from various classes interfere with the structure, function and development of the placenta. As much emphasis should be given to explore the molecular mechanism(s) involved in deleterious effects of chemicals in the placenta as has been given to the fetus or mother.

## ACKNOWLEDGMENTS

The author would like to thank Mrs. Robin B. Doss and Ms. Michelle A. Lasher for their assistance in the preparation of this chapter.

## Dermal toxicity

*Faqir Muhammad and Jim E. Riviere*

### INTRODUCTION

Skin is an essential and dynamic organ. In addition to performing important functions including thermoregulation and preventing insensible water loss, it also has important metabolic, immunological and neurosensory properties. However, the predominant function of skin is to protect the body against a variety of toxicological insults. Animals are relatively less protective against such insults as compared to humans due to lack of clothing, inferior housing and different social interactions. In most instances, the skin of animals directly contacts environmental, chemical and other pollutant exposure without the benefit of man-made protection. Although the largest organ of the body can often face these insults to a certain threshold, animals exhibit symptoms of dermal toxicity when this limit is passed.

Knowledge of the basic structure of skin is necessary to understand the mechanisms of dermal absorption and toxicity of topically applied toxicants. Skin is composed of three distinct layers, namely, epidermis, dermis and hypodermis. Of these layers, the epidermis (consists of keratinocytes and non-keratinocytes) is considered the most important barrier to dermal penetration of most chemicals. The epidermal layers can further be classified from external surface inward as stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum and stratum basale. The stratum basale consists of a single layer of cuboidal or columnar cells resting on basal lamina and is the viable layer of cells in the epidermis. These cells are mitotically active, thus keeping the epidermis replenished as the stratum corneum (SC) cells are sloughed from the surface epidermis (Lavker and Sun,

1983; Monteiro-Riviere, 2006). The approximate cell turnover and self-replacement time in normal human skin is 28 days. This differs widely across species. Mechanical or chemical injuries can increase the mitotic rate of basal cells. Stratum spinosum consists of several layers of irregular polyhedral cells. The cells of this layer have numerous tonofilaments and small membrane bound organelles (lamellar granules). Stratum granulosum consists of several layers of flattened cells containing irregularly shaped, non-membrane bound and electron-dense keratohyalin granules. These granules have a role in keratinization and maintaining the barrier functions of the skin. The lamellar granules contain several types of lipids (ceramides, cholesterol, fatty acids) and hydrolytic enzymes including proteases, acid phosphatases, lipases and glycosidases (Downing, 1992; Monteiro-Riviere, 2006). Stratum lucidum is a thin layer only present in very thick areas of skin such as palmer and plantar surfaces.

The outermost layer of the epidermis is the SC which consists of several layers of completely keratinized dead cells (corneocytes) embedded in an extracellular lipid matrix. This has been depicted as the “bricks and mortar model” where keratinized cells, the bricks, are embedded in the lipid mortar. The dead keratinized cells are highly water absorbent and keep the skin moist and soft. The water-holding capacity of the epidermis is further maintained by sebum (natural oil covering the skin) secretion from glandular structures of the skin. A number of non-keratinocyte cell types are found in skin. The melanocytes are involved in skin pigmentation; Merkel cells act as mechanoreceptors for touch, while Langerhans cells play a major role in the skin immune response. These specialized cells are not involved in barrier functions of skin (Monteiro-Riviere, 2006).

Other specialized regions of the epidermis are the skin appendages which include hair, sweat and sebaceous glands, hoof, claw, nail, feathers and horn. The dermis consists of dense irregular connective tissue with collagen, elastic and reticular fibers in a mucopolysaccharides ground substance. Fibroblasts, mast cells and macrophages are the predominant cells of this layer. In addition, sweat glands, sebaceous glands, hair follicles and erector pili muscles are located in the dermis. The hypodermis is a layer of loose connective tissues beneath the dermis. This layer helps to anchor the dermis to the underlying tissues such as muscle or bone (Monteiro-Riviere, 2006).

SC is considered the primary barrier of skin against the penetration of foreign substances as this layer provides up to 1000 times the resistance to exogenous compounds as compared to the layers beneath it. Disruption of this layer either by physical (tape stripping) or by chemical means will adversely affect the barrier properties. Extraction of these epidermal lipids with organic solvents (Monteiro-Riviere *et al.*, 2001) and jet fuel hydrocarbons (Muhammad *et al.*, 2005b) can reduce the barrier functions of the skin. The other two deeper layers of skin (dermis and hypodermis) offer no resistance to penetration of most compounds. Once a substance has penetrated the epidermis, it will easily traverse the other layers. The potential exceptions are very lipophilic compounds (log lipid to water partition coefficient, greater than four) that may tend to stay in the lipid environment of skin.

## ABSORPTION

Toxicants traverse biological membranes either by passive diffusion or by active transport. A passive diffusion process implies that the solute flux is linearly dependent on the solute concentration gradient; while active transport processes typically involve a saturable mechanism (Friedman, 1986). Dermal absorption is a passive process. Generally, topical absorption involves a sequence of events that include partitioning of the molecule into the SC from the applied vehicle phase, diffusion through the SC, partitioning from the SC into the viable epidermis, diffusion through the epidermis and upper dermis and finally capillary uptake and systemic exposure. Hence, the movement of toxic molecules across the skin involves transport through a series of resistances. In general, for polar toxicants, the diffusional resistance of the SC is large compared to that presented by the viable epidermis and dermis. For more lipophilic molecules, the resistance of the SC is smaller. However, the SC maintains a rate-controlling role since a highly lipophilic molecule does not favorably partition out of the SC into the more aqueous viable epidermis. From the description of

SC components and structure, one can envisage that a diffusing molecule can adopt one or more of the following penetration pathways:

- 1 The intercellular/paracellular path, via the tortuous but continuous intercellular lipids.
- 2 The transcellular path, indicating that the toxicants transfer sequentially and repeatedly through the "bricks" and "mortar."
- 3 The transappendageal path via hair follicles, sweat pores, etc.

Most molecules follow the first penetration pathway, yet the absorption of certain compounds can take place via a transfollicular path or sweat pores, often resulting in skin penetration (residing within skin) rather than true absorption (systemic exposure). Both absorption and penetration are important determinants of direct chemical toxicity to the skin. Diffusion occurs through the intercellular lipids, hence partitioning into these lipids is often the primary determinant of absorption. Species differences in lipid makeup thus also translate into species differences in absorption.

Percutaneous absorption through the intercellular pathway of the SC is driven by passive diffusion down a concentration gradient described at steady state by Fick's law of diffusion (Riviere, 1999):

$$\text{Flux} = [(D \cdot PC \cdot SA) / H](\Delta x)$$

where  $D$  is the diffusion coefficient and  $PC$  is the partition coefficient,  $SA$  is the applied surface area,  $H$  is membrane thickness (or more precisely the intercellular path length) and  $\Delta x$  is the concentration gradient across the membrane. Since *in vivo* blood concentrations after absorption are negligible compared to applied surface concentration,  $\Delta x$  reduces to the concentration ( $C$ ). It is this relationship that allows the prediction of compound flux across the skin to be correlated to factors predictive of  $D$  and  $PC$  (e.g., octanol/water partition coefficients reflecting chemical partitioning into the SC lipids). Flux is expressed in terms of applied surface area, often normalized to  $\text{cm}^2$ .

The term  $(D \cdot PC / H)$  is compound dependent and is termed the permeability coefficient ( $K_p$ ), reducing the determination of flux to  $K_p \cdot \Delta X$  or  $K_p \cdot C$ , a first-order pharmacokinetic equation ( $dx/dt = kX$ ). Rearrangement of this equation yields the primary method used to experimentally determine  $K_p$ :

$$K_p = \text{steady state flux / concentration}$$

It must be stressed that both transdermal flux and  $K_p$  are not only chemical dependent, but also tightly

constrained by the membrane system studied as well as the method of topical application (neat compound, vehicle, length of experiment, etc.). The PC that is integral to  $K_p$  is the PC between the surface or applied vehicle and the SC. Different vehicles will thus result in different PCs. Similarly, skin from different species may result in different PCs due to differences in the SC lipids and intercellular path lengths.

Cutaneous biotransformation of drugs is also a barrier to absorption of certain compounds, and has been used to promote the absorption of certain chemicals (pro drugs) across the skin. This aspect is important in skin toxicology as non-toxic parent compounds may be bioactivated within the epidermis, such as benzo[a]pyrene to an epoxide (Riviere, 1999).

There are numerous factors that can affect the dermal toxicity in animals. These include the species, breed, age, health status, skin condition (dryness, hairiness or thickness) and local environment (weather, humidity, temperature). Some of these factors including epidermal thickness, epidermal cell size, number of cell layers and blood flow patterns can vary between species as well as within the species (Monteiro-Riviere *et al.*, 1990). As a general rule, young and emaciated animals are more prone to dermal intoxication than are adults or healthy animals. In this chapter, the agents involved in dermal toxicity directly or indirectly are described. There are a variety of compounds including pesticides, polycyclic aromatic hydrocarbons (PAHs), volatile organic compounds (VOCs), heavy metals, photosensitizing agents and toxic plants that can affect the skin of animals by multiple mechanisms.

## PLANTS CAUSING DERMAL TOXICITY IN ANIMALS

Exposure to plant toxins may be the most common cause of dermal toxicity in animals, since the majority of production animals are reared on pastures where they come in contact with various types of vegetation. Some plants have compounds that directly affect the skin after contact, while others have thorns/spines that can cause mechanical injury to the skin. Many compounds may induce allergic dermatitis, similar to poison ivy in humans. A discussion of contact sensitization is beyond the scope of the present chapter. A text in immunology or allergy medicine should be consulted. Many plants have pigments or compounds that once absorbed from the gastrointestinal tract, induce a direct effect on non-pigmented skin when exposed to light. Other plants can result in a secondary photosensitization by virtue of toxic alkaloids that cause irreversible liver disease.

## PHOTOSENSITIZATION

Photosensitization is a severe dermatitis resulting from a complex reaction induced by plant pigments exposed to ultraviolet (UV) sunlight in the skin of animals that have eaten certain plants (Rowe, 1989). UV radiation can induce acute or chronic photobiologic reactions in the absence of exogenous chromophores such as nuclear DNA (Horio *et al.*, 2005). Non-pigmented skin gives the most severe reaction where these reactive compounds are directly exposed to UV light, most likely secondary to light-enhanced photooxidation. The amino acids susceptible to oxidation (histidine, tyrosine and tryptophan) once oxidized evoke an intense inflammatory response in the blood vessels and surrounding cells resulting in tissue necrosis. In addition to plant pigments, fungal toxins and certain chemicals can induce photosensitization. Quite frequently horses and cattle develop photosensitization during grazing on pasture which may be due to oxidative damage in photodynamic therapy (Clare, 1955; Babilas *et al.*, 2005). Similarly outbreaks of facial eczema (pithomycotoxicosis), a hepatogenous photosensitization caused by the mycotoxin sporidesmin, have been reported in ruminants in the Azores Islands of Portugal (Pinto *et al.*, 2005).

Photosensitization may be classified into primary and secondary types (Table 21.1). Primary photosensitization is associated with photodynamic compounds in certain plants, which react in the non-pigmented skin with UV light to cause a severe dermatitis. Secondary photosensitization results when an animal's liver is sufficiently diseased to be unable to remove plant byproducts that can react with UV light to cause photosensitization. Phylloerythrin, a bacterial breakdown product of chlorophyll, is a potent photosensitizing compound. Normally phylloerythrin is removed by the liver and is excreted in the bile, but if the liver is severely diseased, it accumulates in the blood to cause photosensitization if a white skinned animal is exposed to UV light. Secondary photosensitization is much more common in livestock than primary photosensitization.

Primary photosensitization develops when animals eat plants having polyphenolic pigments. Historically, two plants, buckwheat (Kingsbury, 1964) and St. John's wort (Marsh, 1930; Araya and Ford, 1981), are associated with primary photosensitization. Bishop's weed (*Ammi majus*), rain lily (*Cooperia pedunculata*), spring parsley (*Cymopterus watsonii*), buckwheat (*Fagopyrum esculentum*), giant hogweed (*Heracleum mantegazzianum*), St. John's wort (*Hypericum perforatum*) and Dutchman's britches (*Thamnosma texana*) are reported as primary photosensitizing plants (Knight and Walter, 2003). These plant species (Table 21.1) contain photodynamic furanocoumarin compounds that have been associated with

TABLE 21.1 Important plants causing photosensitization in animals

Common name	Botanical name	Type of photo-sensitivity
St. John's wort	<i>Hypericum perforatum</i>	Primary
Spring parsley	<i>Cymopterus watsonii</i>	Primary
Bishop's weed	<i>Ammi majus</i>	Primary
Dutchman's britches	<i>Thamnosma texana</i>	Primary
Rain lily	<i>Cooperia pedunculata</i>	Primary
Groundsels, Senecio	<i>Senecio</i> spp.	Secondary
Fiddle neck	<i>Amsinckia</i> spp.	Secondary
Rattle box	<i>Crotolaria</i> spp.	Secondary
Hound's tongue	<i>Cynoglossum officinale</i>	Secondary
Blue weed	<i>Echium vulgare</i>	Secondary
Lantana	<i>Lantana camara</i>	Secondary
Panic grasses	<i>Panicum</i> spp.	Secondary
Horse brush	<i>Tetradymia</i> spp.	Secondary
Alsike clover	<i>Trifolium hybridum</i>	Secondary
Black sage	<i>Artemisia nigra</i>	Secondary
Puncture vine	<i>Tribulus terrestris</i>	Secondary

photosensitivity through ingestion and direct contact with the skin (Dollahite *et al.*, 1978; Oertli *et al.*, 1983). A seasonal photosensitivity of cattle, associated with the consumption of the dead leaves of rain lily has been reported in southeast Texas (Rowe *et al.*, 1987; Casteel *et al.*, 1988). Similarly, giant hogweed (*Heracleum mantegazzianum*) and cow parsnip (*Heracleum* spp.) are also known to cause photosensitivity in Europe and North America, respectively (Knight and Walter, 2003).

Secondary photosensitization is primarily caused by a variety of compounds toxic to the liver that are found in plants, the most important of which are the pyrrolizidine alkaloids (PAs). There are four important plant genera, namely, *Senecio*, *Crotolaria*, *Cynoglossum* and *Amsinckia*, which cause liver disease and secondary photosensitization in North America (Table 21.1). Most PA poisoning of livestock in the western United States is attributable to three species of *Senecio*: tansy ragwort (*S. jacobaea*), threadleaf or wooly groundsel (*S. douglasii* var. *longilobus*) (Johnson and Molyneux, 1984; Johnson *et al.*, 1989) and Riddell's groundsel (*S. riddellii*) (Johnson *et al.*, 1985; Molyneux *et al.*, 1991). *Senecio* species are also the most common cause of PA poisoning throughout the world (Lombardo de Barros *et al.*, 1992; Odriozola *et al.*, 1994). Fiddleneck (*Amsinckia intermedia*), and hound's tongue (*Cynoglossum officinale*), members of the Boraginaceae, have significant quantities of PA capable of producing secondary photosensitization in cattle and horses (John *et al.*, 1974; Stegelmeier *et al.*, 1994). The PA content of plants varies considerably, generally increasing with maturation of the plant and reaching a maximum just before the flower buds open (Candrian *et al.*, 1984). Flowers have the greatest amount of the alkaloid, while seeds of *Crotolaria* and *Amsinckia* concentrate high levels of PA (Johnson and Smart, 1983; Nobre *et al.*, 1994). Pigs

are the most susceptible to PA poisoning, followed by poultry, cattle, horses, goats and sheep (Mattocks, 1968; Craig *et al.*, 1992).

A variety of plant toxins other than PAs are also involved in secondary photosensitization. Among these, horse brush (*Tetradymia glabrata* and *T. canescens*) has been attributed to cause secondary photosensitivity in sheep in North America (Johnson, 1974; Flemming *et al.*, 1922). However, sheep are much more susceptible to horse brush photosensitivity if they concurrently browse on black sage (*Artemisia nigra*), big sage (*A. tridentata*) or both (Flemming *et al.*, 1922; Johnson, 1974). These plants frequently grow in the same locations in western range-lands, and when eaten together have a synergistic effect in causing photosensitivity. Certain plant species like *Lantana camara*, *Agave lecheguilla*, *Tribulus terrestris* and *Panicum* grass species cause secondary photosensitization through inflammation and obstruction of the biliary system (Knight and Walter, 2003). These photosensitizing plants contain saponins that cause inflammation and obstruction of the bile ducts. When the liver cannot excrete bile normally, photosensitizing compounds will accumulate in the blood of animals and will result in photosensitization (Radostits *et al.*, 1994). Sheep eating puncture vine (*Tribulus terrestris*) develop photosensitivity secondary to biliary obstruction that was initially thought to be caused by a mycotoxin, but later found to be the result of steroidal saponins in the plant (Glasonbury and Doughty, 1984; Kellerman *et al.*, 1994). An outbreak of photosensitization in sheep in Great Britain and western Europe due to bog asphodel (*Nartheicum ossifragum*) was caused by plant saponin that occluded the biliary system (Pass, 1987; Burrows, 1990). Alsike clover (*Trifolium hybridum*) is a perennial legume that is commonly grown for livestock consumption in northern parts of North America. This plant can cause secondary photosensitivity in horses that can be attributed to the accumulation of phyloerythrin in the horse's circulation as a result of liver failure (Nation, 1991; Colon *et al.*, 1996).

Animals can also develop photosensitivity while eating moldy grains containing hepatotoxic mycotoxins (aflatoxins) produced by fungi belonging to the genera of *Aspergillus* and *Penicillium*. Moldy straw and water-damaged alfalfa hay may also cause photosensitivity in cattle as a result of mycotoxins that induce hepatitis and cholangitis (Richard, 1973; Putnam *et al.*, 1986; Scruggs and Blue, 1994). Feeding moldy alfalfa hay and silage to cattle has been associated with a secondary photosensitivity due to liver toxins produced by a variety of fungi cultured from the hay (House *et al.*, 1996). However, cattle appear to be more susceptible to these unidentified toxins as compared to sheep, goats and horses (Casteel *et al.*, 1994).

Blue-green algae or cyanobacteria, reported to cause poisoning in North America, include members of the

genera *Microcystis*, *Anabaena* and *Aphanizomenon*. These organisms release potent toxins into the water that can cause severe poisoning in animals drinking the contaminated water. Some of these toxins can act on the liver to cause liver failure and photosensitization (Beasley *et al.*, 1989a, b; Osweiler *et al.*, 1985a; Hoover and Smith, 1995). Southdown sheep may also develop photosensitivity due to a congenital defect in the liver's ability to excrete the photoreactive compound phyloerythrin (Hancock, 1950). In addition to plants, certain drugs and chemicals such as phenothiazine sulfoxide, some tetracycline antibiotics and psoralen, which employs this toxic property as a mechanism of its therapeutic effect to treat conditions such as psoriasis, also produce photosensitivity in animals.

Some molds are not only photosensitizing, but may be toxic to the skin of animals directly or indirectly by other mechanisms. Ergot alkaloids can induce gangrene in all species of animals if ingested over a period of several days or weeks. The most commonly involved fungus is *Claviceps purpurea*. The distal extremities, tail, ears and nose may slough away during this disease. Other mold toxins like serotoxins (trichothecene toxin T-2) have the ability to irritate the skin and mucous membranes of animals on contact. Stomatitis, oral ulcers and necrosis of areas of skin that are in direct contact with moldy plant may be seen in the affected animals. Another trichothecene toxin produced by *Fusarium tricinctum* is diacetoxyscirpenol. It may cause dermal necrosis and gangrene in cattle fed on moldy corn. Acute fescue (a common pasture grass in United States) toxicosis in cattle resembles gangrenous ergotism. In this condition, animals can develop dry gangrene of the extremities. The clavicipetaceous fungi are mostly present in fescue pasture. Fescue hay and seed infected with this mold are reported to be toxic to cattle (Jackson *et al.*, 1984).

## TOPICAL CHEMICALS CAUSING DERMAL TOXICITY IN ANIMALS

Skin is the second most frequent route by which chemicals enter the body of animals. Liquid chemicals are generally absorbed well through the skin if they can partition into the SC lipids. Chemicals in the forms of solids, gases and vapors are only absorbed through the skin if they are first dissolved in the moist layer at the surface of the skin. The skin is a major target for gaseous and liquid pollutants. Various allergic or inflammatory conditions of skin including eczema, atopic dermatitis or acne are often observed on exposure to various chemicals (Baudouin *et al.*, 2002). The topical chemicals that react most specifically with the skin are PAHs, VOCs,

pesticides and heavy metals. A great deal of research has been conducted on experimental exposures to the common laboratory animals as components of mechanistic carcinogenesis studies or as a component of human risk assessments. Unfortunately, less is known about mechanisms of actions of compounds of veterinary importance.

## PAHs

PAHs including benz[a]anthracene, benzo[b]fluoranthene, benzo[j]fluoranthene, benzo[k]fluoranthene, benzo[a]pyrene, dibenz[a,j]acridine, dibenz[a,h]acridine, dibenz[a,h]-anthracene, -dibenzo[c,g]carbazole, dibenzo[a,e]pyrene, dibenzo[a,h]pyrene, dibenzo[a,i]pyrene, dibenzo[a,l]pyrene, indeno[1,2,3-cd]pyrene and 5-methylchrysene are reported to cause toxicity in experimental animals (IARC, 1987). Most of these PAHs have been studied in biomedical, biochemical and other laboratory-based experiments. Out of these 15 PAHs, at least eight are present in coal tar that is used as a fuel in the steel industry and blast furnaces. Coal tar is also used in the treatment of skin diseases like dermatitis, psoriasis and eczema. Coal tar can cause allergic or irritant contact dermatitis, erythema, stinging, precipitation of exfoliative dermatitis or generalized pustular psoriasis, tar folliculitis, atrophy, telangiectasia, pigmentation, cutaneous horns, keratoacanthomas and tar warts (Andrew and Moses, 1985; Burden *et al.*, 1994). Coal tar pitch is used for roofing, surface coatings and a variety of other applications (IARC, 1983); three out of these 15 PAHs are found in bitumen and asphalt that are used for paving roads, water proofing and coating pipes. Therefore, considerable risk exists for the animals to come in contact with these toxic PAHs in these localities/applications. Animals are exposed to PAHs through inhalation, eating fodders grown on contaminated soils or through skin when in contact with PAH-contaminated soil or products such as heavy oils, coal tar and roofing tar or creosote (a wood preservative). The toxic levels of PAH have been measured in various tissues of fish that are supposed to be absorbed through the skin (Oliveira-Ribeiro *et al.*, 2005).

When administered topically, benz[a]anthracene and benzo[j]fluoranthene induced skin papillomas in mice while benzo[k]fluoranthene was active as an initiator of skin tumors in female mice (IARC, 1983). Benzo[a]pyrene induced skin papillomas and carcinomas in mice, rats, guinea pigs and rabbits. Dibenz[a,j]acridine has also been reported to cause skin tumors in mice. Whereas dibenzo[a,e]pyrene, dibenzo[a,h]pyrene, dibenzo[a,i]pyrene and 5-methylchrysene produced skin tumors in mice when applied topically (IARC,

1973). To date, dibenzo[*a,i*]pyrene has been found to be the strongest tumor-initiating PAH ever tested in rodent skin and mammary tumor models (Mahadevan *et al.*, 2005). However, the tumor promoting potential of benzo[*a*]pyrene can be increased many folds in combination with other toxic chemicals. For example, the combinations of benzo[*a*]pyrene and UV-A light (Wang *et al.*, 2005), or benzo[*a*]pyrene and arsenic (Fischer *et al.*, 2005) treatment synergistically increased tumor incidence and multiplicity in hairless mouse skin. It has been reported that cytochrome P450 1B1 determines susceptibility to dibenzo[*a*]pyrene-induced tumor formation (Buters *et al.*, 2002). However, the organic extracts of black raspberries can inhibit benzo[*a*]pyrene-induced cell transformation *in vitro* possibly by inhibiting the transactivation of activated protein-1 and nuclear factor kappa-B (Huang *et al.*, 2002).

Chlorinated PAHs such as polychlorodibenzodioxines and polychlorofuranes are found in impurities in certain pesticides or as secondary residues in industrial processes. These halogenated PAHs are very toxic for the skin and can cause chloride acne (Baudouin *et al.*, 2002). In a recent incident, former Ukraine Prime Minister and Presidential Candidate Victor Yushchenko developed chloracne from dioxin poisoning. This mysterious poisoning had left his face pockmarked and ashen.

Skin can act as a storage organ for certain halogenated PAHs like hexachlorobiphenyl (Di Francesco *et al.*, 1988). The halogenated PAHs are oily compounds, which can obstruct the pores of the skin, thus resulting in accumulation of sebum and keratin, leading to the formation of cysts. This hypothesis was supported with hyperkeratinization observed around the follicles along with involution of the sebaceous glands by topically applied 2,3,7,8-tetrachlorodibenzo-*p*-dioxin to mouse skin (Panteleyev *et al.*, 1997).

The skin is particularly active in the metabolism of PAHs. Some PAHs are activated by epidermal cytochrome P450 and hydrolases to generate epoxides and diols, active metabolites able to bind to DNA and initiate the processes of carcinogenesis. Other PAHs cause the skin toxicity by different mechanisms. For example, topical application of 7H-dibenzo[*c,g*]carbazole caused the appearance of DNA adducts in mouse skin (Schurdak and Randerath, 1989). Another study exhibited the potentiating effect of iron on 7,12-dimethylbenz[*a*]anthracene in the mouse skin. In addition to genotoxic effects of this PAH, the resulting oxidative stress makes this association tumorigenic in the skin tissue (Rezazadeh and Athar, 1997). The photoactivation of certain PAHs like 2-nitrofluorene by UV radiations in rats can generate intermediates that can bind covalently to RNA and to the skin proteins. This association of 2-nitrofluorene and UV-A is mutagenic and could cause skin cancers (Wierckx *et al.*, 1992).

**FIGURE 21.1** Epidermal thickness (mean + SEM) after 1 and 4 days of exposure to *in vivo* JP-8 or constituent aliphatic hydrocarbons in pigs. Note the maximum toxic *in vivo* response with tridecane (C-13) and tetradecane (C-14) hydrocarbons.

## VOCs

VOCs such as hydrocarbons, ketones, aldehydes, solvents (benzene, fluorocarbons) and gases (methane) are generated from automobiles and industries. Certain VOCs such as benzene are highly genotoxic, inducing cancers in various tissues. Other VOCs can cause precancerous lesions in the lungs and in the skin (Michielsen *et al.*, 1999). Some VOCs can produce inflammatory mediators in cultured epidermal keratinocytes. These mediators such as interleukin-8 and -1 $\beta$  are significantly increased and could favor the allergic/inflammatory reactions as in atopic dermatitis or eczema (Ushio *et al.*, 1999).

Certain VOCs present in jet fuel like ethyl benzene, o-xylene and naphthalene did not produce direct skin irritation in pigskin (Muhammad *et al.*, 2005a). Interestingly, these three hydrocarbons had higher absorption through pigskin compared to other aromatic and aliphatic hydrocarbons studied. Transmission electron microscope and Fourier transform infrared spectroscopy indicated that these PAHs have the potential to extract the lipids out of the SC of skin thus affecting the skin's permeability barrier and increasing the absorption of exogenous substances (Muhammad *et al.*, 2005b). On the other hand, less volatile hydrocarbons of jet fuels such as tridecane, tetradecane and pentadecane produced significant direct dermal irritation and microscopic changes in pigskin (Figure 21.1).

Polychlorinated naphthalenes are present in lubrication greases, oils, fuels and in wood preservatives. Chlorinated naphthalenes can cause severe

hyperkeratosis in cattle. The most prominent lesions were observed on the neck and wither but may affect the entire integument. This dermal toxicity in cattle needs to be differentiated from avitaminosis A. Chlorinated naphthalenes did not produce hyperkeratosis in sheep and swine (Clarke and Clarke, 1975). Ethylene glycol monomethyl ether (EGME) and its acetate ester (EGMEA) are moderately volatile liquids with very good solubility properties. They are used in paints, lacquers, stains, inks and surface coatings and as an anti-icing additive in hydraulic fluids and jet fuel. EGME and EGMEA are efficiently absorbed via dermal penetration. Skin absorption in animals may contribute substantially to the total uptake following skin contact with liquids or vapors containing EGME or EGMEA (Johanson, 2000).

## PESTICIDES

The word “pesticide” in this chapter will encompass various relevant chemicals including insecticide for controlling termites or fleas, herbicides for ridding the crops/lawn of dandelions or fungicides that protect plants during fungal diseases. Despite oral ingestion, dermal absorption is the major source of pesticide exposure in occupational, agricultural and veterinary settings, a topic recently reviewed (Riviere, 2006). Since most of the pesticides are highly lipophilic, their penetration and accumulation in skin with resulting local dermal irritation and/or mild to severe systemic toxic effects in the exposed animals cannot be overlooked.

Livestock and pet animal exposure to pesticides is usually accidental. The most common source of dermal toxicity induced with insecticides in both large and small animals is the miscalculation of concentrations for spraying and dipping procedures. A misplaced decimal point can result in hundred- or thousand-fold increase in exposure. A common source of non-recommended exposure to animals is the inadvertent mixing of powdered pesticides, mistaken for salt or mineral preparations, into animal feeds. A low-level contamination of animals by insecticides can also occur with the use of persistent chlorinated hydrocarbons such as dichlorodiphenyl-trichloroethane (DDT), aldrin, dieldrin and heptachlor, etc. on crops which may be used for animal feeds. These insecticides may persist in soil for several years. Thus, forage crops grown on such soils could be sufficiently contaminated to produce toxic effects in animals. Other sources of insecticide exposure in animals include carelessness in leaving insecticides accessible to animals, leaving insecticide preparations on sills of sheds or barns, inadequate covers on back rubbers containing insecticide concentrates, or using pesticide containers to

water and feed animals without proper decontamination (Osweiler *et al.*, 1985b). Thus, animals can exhibit signs of dermal toxicity after oral or systemic exposure to pesticides. On the other hand, washing the skin of humans or animals after exposure to a pesticide or other chemical may leave a major portion of the dose on/in the washed skin. This skin residue can contribute to the toxicity of a pesticide by continued post-wash absorption (Zendzian, 2003). According to recent statistics on occupational dermatosis among private farmers, pesticides are the causative factor in 18% of skin disorders (Spiewak, 2003). The other most frequently identified causative factors for occupational dermatosis were plant dusts (38%), animal allergens (36%), metals (29%) and rubber chemicals (15%).

Certain organophosphorus insecticides such as chlorpyrifos have been shown to exert their systemic effects in the form of cholinesterase inhibition after dermal application to rats (Abu-Qure *et al.*, 2001). The topical application of chlorpyrifos and cypermethrin to rats showed an inhibition of acetylcholinesterase and butyrylcholinesterase activity in the brain (Latuszynska *et al.*, 2001). Another study suggested that skin could act as a reservoir and may release chlorpyrifos over a prolonged period (Griffin *et al.*, 2000). Pyrethrins are insecticides that are derived from the extract of chrysanthemum flowers. The synthetic forms of pyrethrins are called pyrethroids. The initial plant extract (crude pyrethrum) contains about 30–35% pyrethrins. Allergic contact dermatitis has been observed in sensitized and non-sensitized guinea pigs by topical exposure to various extracts from pyrethrum flowers (Rickett *et al.*, 1972). Occupationally, skin is the main route of pyrethroid absorption. The major toxic effect of dermal exposure is paraesthesiae, presumably due to hyperactivity of cutaneous sensory nerve fibers (Bradberry *et al.*, 2005). The face is most commonly affected and the paraesthesiae are exacerbated by sensory stimulation such as sunlight, scratching, heat, sweating or water application. The specific treatment is not generally required, as paraesthesiae usually resolve in 12–24 h. Topical application of dl- $\alpha$  tocopherol acetate (vitamin E) may reduce the severity (Bradberry *et al.*, 2005). Similarly, cypermethrin (a pyrethroid) can penetrate through the skin of animals and can exert its systemic effects (Latuszynska *et al.*, 2001). Dermal exposure to permethrin (another pyrethroid) has often been considered a mitigating factor in Gulf War Syndrome (Riviere *et al.*, 2002). Studies have shown that systemic exposure of certain chemicals such as diisopropyl fluorophosphate (DFP) or pyridostigmine bromide and topical application of DFP or *N,N*-diethyl-*m*-toluamide (DEET) can alter the disposition of [<sup>14</sup>C] permethrin in skin and possibly its bioavailability in soldiers simultaneously exposed to these chemicals (Baynes *et al.*, 2002a).

A number of chemicals are used as fumigants for control of insects, nematodes, fungi and weeds in soils, stored grains, feedstuffs, storage spaces in mills and common carrier vehicles. Most of the toxicology of such chemicals is studied in laboratory animals and needs to be extrapolated for the domestic animals. One such chemical, ethylene dichloride, is reported as irritating to the skin and mucous membranes. It can be absorbed through the skin although large doses are required to cause toxicosis in animals. Ethylene dibromide and metham-sodium are other skin irritants that also have the potential to absorb through the skin. Fluoroacetate was developed for insecticide and rodent control applications in early 1940s. This chemical has been reported to absorb through the abraded skin but not through the intact skin (Osweiler *et al.*, 1985b). Paraquat is a non-volatile bipyridyl herbicide and is insoluble in water. Low-to-moderate amounts of bipyridyl herbicides are absorbed from the skin of animals. Direct contact of animals with paraquat results in irritation to skin (Longstaffe *et al.*, 1981). Experimental studies in pigskin demonstrated epidermal toxicity in the absence of appreciable transdermal absorption (Srikrishna *et al.*, 1992).

Many chemicals and solvents are dermal penetration enhancers. Such chemicals may increase dermal penetration by damaging the skin's barrier, by modifying the SC, or by promoting the partitioning of co-penetrating chemicals (Moser *et al.*, 2001; Medi *et al.*, 2006). This scenario may serve useful purposes in transdermal drug delivery but at the same time penetration enhancers may also increase skin penetration of harmful chemicals (Baynes *et al.*, 2002a). The percutaneous penetration of five pesticides having different solubilities was studied through a slightly damaged skin. It was observed that the percutaneous penetration of the most hydrophilic compounds will be affected most, and may significantly affect the rate, lag-time as well as total penetration of chemicals (Nielsen, 2005). A combination of two solvents, pyridostigmine bromide and DFP, increased the dermal absorption of DEET through isolated perfused porcine skin (Riviere *et al.*, 2003). Earlier studies by Baynes *et al.* (1997) reported that the extent of DEET absorption was greater with dimethyl sulfoxide (DMSO) and acetone than with ethanol in rat and mouse skin. These studies support that DEET can have sufficient systemic exposure to potentially cause signs of toxicity when simultaneously applied with pesticides such as permethrin or carbaryl. Thus, penetration enhancement can have undesirable consequences. In this context, commercial sunscreen formulations are found to significantly increase the transdermal penetration of a herbicide 2,4-dichlorophenoxyacetic acid in *in vitro* rat skin (Pont *et al.*, 2004). In addition to the active ingredients, "inert" ingredients in sunscreen or pesticide formulations may also be responsible for controlling the transdermal

penetration of herbicide 2,4-dichlorophenoxyacetic acid (Pont *et al.*, 2003) and carbamate insecticide carbaryl (Baynes and Riviere, 1998), respectively.

Pentachlorophenol (PCP) has been widely used as a pesticide. The persistence of PCP in soil and water and apparent widespread use has resulted in significant exposure to animals. Young swine have died following dermal exposure to freshly PCP treated wood used in farrowing crates or farrowing houses. *In vivo* studies in swine demonstrated that exposure to PCP-contaminated soil can result in significant dermal absorption of the pesticide (Wester *et al.*, 1993; Qiao *et al.*, 1997). It has been demonstrated that the presence of solvent and/or surfactant mixtures can influence PCP absorption in the isolated, perfused porcine skin flap (IPPSF) (Riviere *et al.*, 2001). Baynes *et al.* (2002b) demonstrated that PCP is fairly well absorbed across porcine skin. PCP absorption in skin was greater in water or water-based mixtures than in 100% ethanol. PCP is barely soluble in water, but this pesticide is more likely to partition from water than an organic solvent vehicle such as ethanol into the SC. This situation warrants the dermal uptake of lipophilic pesticides through the skin of animals as the latter have free access to water all the time. Both PCP and its major metabolite tetrachlorohydroquinone (TCHQ) could induce mice skin epidermal hyperplasia and proliferating cell nuclear antigen (PCNA) labeling index in the epidermis. However, TCHQ caused a more significant induction of epidermal hyperplasia and PCNA positive cells than PCP. Furthermore, topical application of PCP induced significant organ enlargement and lymphoma in mice (Chang *et al.*, 2003).

The insecticide D-limonene toxicosis has been rarely described in canine species. One study has reported skin lesions consisting of coalescing erythematous patches in the cat groomed previously with a D-limonene-based insecticidal shampoo. Dermatohistopathologic changes included multifocal areas of acute coagulative epidermal necrosis (Lee *et al.*, 2002). Epichlorohydrin (ECH) is one of the more commercially important aliphatic epoxides used extensively as an insecticide, an industrial intermediate and as a laboratory reagent. It is a volatile, colorless liquid and behaves as an alkylating agent. Reports have shown that it causes dermal toxicity in animals (Giri, 1997). Dodecen-1-ol (an insect attractant) acted as a primary skin irritant, since it caused superficial chemical burns (Beroza *et al.*, 1975). Ortho-phenylphenol (OPP) and its sodium (SOPP) and potassium (POPP) salts are used as fungicides and disinfectants. OPP has been reported as irritating, and SOPP and POPP as corrosive for the skin and mucous membranes (Bomhard *et al.*, 2002).

White phosphorus had been used to prepare rodenticides that are generally mixed with a greasy or oily base. Skin irritation or burning may occur from dermal

exposure to high concentrations of such rodenticides but absorption is not observed with dermal exposure. Thallium is another rodenticide that is primarily used by government agencies. In subacute thallium poisoning in dogs and cats, reddening and pustule formation in the skin starting from the ears and nose and progressing to the axilla, abdomen and the rest of the body, associated with loss of hair, was reported. In chronic thallium poisoning, skin hyperkeratosis, parakeratosis, hyperemia and vivid discoloration of skin have been observed in the cat (Osweiler *et al.*, 1985b).

## DETERGENTS, SOLVENTS, CORROSIVES AND OTHER HOUSEHOLD PREPARATIONS

Several daily use products (soaps, detergents, drain cleaners; acids, alkalis, etc.) available in homes and other work places may cause dermal irritation. There is scarce information in literature regarding toxicosis due to these daily use products in animals. We will discuss briefly the possibilities of dermal irritation in animals based on well-known scientific principles and published reports.

The evaluation of cleansing products depends upon their cleansing properties (detergent or adsorptive), on the rinsability of the product, on the amount and nature of the additives and on the general and specifically epidermal toxicity of the components (Raab, 1990). In this context, one such preparation is denture cleaner in which the major toxic component is sodium perborate which decomposes to form hydrogen peroxide and sodium borate. These products are strongly alkaline, very irritating to the skin and mucous membranes, and thus can produce dermal toxicity in exposed animals. Similarly, constant or repeated exposure of skin to anionic detergents (sulfomated or phosphorylated hydrocarbons) causes irritation with the removal of natural oils and can result in thickening of skin along with weeping, cracking, scaling and blistering (Dreisbach, 1983). There is evidence that detergent substances are important components of cleansing materials, but their detergent cleansing action may also result in skin toxicity (Marks and Dykes, 1990). Non-ionic detergents such as alkyl and aryl polyether sulfates, alcohols or sulfonates are comparatively less irritating than ionic ones. The acute skin irritation potential of various detergent formulations can be assessed with a patch test (Robinson *et al.*, 2005). In this test, the time of exposure required for 50% of subjects to show a positive skin reaction ( $TR_{50}$  value) is calculated for each product. Using this approach, 24 detergent preparations were tested in seven individual studies. The dermal irritation profiles

could be categorized as follows (by decreasing irritancy): mold/mildew removers (average  $TR_{50} < 0.37h \geq$  disinfectants/sanitizers (0.64h) > fabric softener concentrate (1.09h) < aluminum wash (1.20h) > 20% SDS (1.81h)  $\geq$  liquid laundry detergents (3.48h)  $\geq$  liquid dish detergents (4.16h) < liquid fabric softeners (4.56h) < liquid hand soaps (4.58h) < shampoos (5.40h) = hard surface cleaners (6.34h) > powder automatic dish detergents (>16h) < powder laundry detergents (>16h) (Robinson *et al.*, 2005). Cleansing can also be accomplished with non-detergent containing cleaners (Marks and Dykes, 1990). Drain cleaners consisting of high concentrations (25–36%) of sodium hydroxide and sodium hypochlorite are extremely toxic and caustic to the skin. Direct skin contact to these agents causes coagulative to liquefaction necrosis by dissolving proteins and saponifying lipids. Soaps have been used for thousands of years as part of daily life; however, they are limited by their irritancy to the skin due to their alkaline nature and their tendency to form insoluble and inactive salts when combined with either hard water or sea water (Kirsner and Froelich, 1998).

Calcium cyanide, which is a special constituent of fertilizers, may act as a contact irritant causing skin ulcers. Chlorobromomethane (a fire extinguisher liquid) causes intense skin irritation from exposure to either liquid or its vapors, although this chemical has low dermal absorption. Skin contact to another chemical methyl bromide (used in fire extinguishers, refrigerants or fumigants) can result in irritation and vesiculation. Clinical poisoning may occur from its skin absorption (Osweiler *et al.*, 1985b). Liquid soldering fluxes mainly contain zinc chloride and a high proportion of hydrochloric acid. These components are caustic or corrosive and acute exposure results in direct irritation to skin. Glues and adhesives are often supplied in hydrocarbon solvents. Dermal exposure to these preparations may also produce irritation. The corrosive activity of hypochlorite (a common component of laundry bleaches) on skin is due to oxidizing potency or available chlorine. Alkalinity of some preparations may contribute to tissue injury. Metal cleaners and oven cleaners contain components like soda/potash and KOH/NaOH in high concentrations, respectively, in addition to petroleum-based solvents. All these components would be expected to cause dermal irritation. Ethylene glycol and propylene glycol (PG) are used in most of the topical pharmaceutical and cosmetic preparations as solvents. The localized dermal effects from both solvents are mild, while the published data suggested that PG might have a skin contact sensitization potential (Lakind *et al.*, 1999).

The alkalis present in oven cleaners may cause severe necrotic lesions similar to drain cleaners. Domestic animals, especially pets, may be exposed dermally to paints and varnish removers containing mixtures of

benzene, methanol, acetone and toluene. These solvents can absorb through the skin in considerable amounts. Certain perfumes can cause local irritation of skin. This is probably due to alcohol serving as the primary vehicle. Rubbing alcohol (ethyl alcohol) may sometimes cause cutaneous hyperemia. Rust removers whose major toxic components are hydrochloric acid, phosphoric acid, hydrofluoric acid, etc. can have direct corrosive and necrotizing action like other acids. Most shampoos would not be expected to cause severe dermal irritation. Generally, skin exposures to acids, alkalis and phenols may lead to lesions that can vary from mild dermatitis to severe corrosion of the skin.

## SYSTEMIC COMPOUNDS CAUSING DERMAL TOXICITY IN ANIMALS

### Heavy metals

Metals are intrinsic in nature and are utilized by animals for many essential functions. As a rule, metals are required for life and health in small quantities but are toxic in excessive amounts. The toxic heavy metals in animals include arsenic, lead, cadmium, chromium and nickel. These metals contaminate the environment from industrial, automobile and pesticide activities. The moderately toxic metals are iron, zinc, selenium, mercury and copper. Redistribution of metals in the environment is mainly responsible for access of animals to toxic metals not normally assessable. Metal toxicosis in animals results from the systemic administration of metals. The mechanisms involved in the toxicity of certain metals like cadmium, chromium and nickel have indicated that these metals act directly or indirectly on intracellular proteins in the skin (Carlisle *et al.*, 2001). Inorganic arsenic exposure in drinking water is linked to skin, bladder and lung cancer. The mechanism of arsenic-induced cancer is not clear, but it is proposed that arsenic can generate reactive oxygen species, suggesting that oxidation of DNA may play a role in carcinogenesis (Fischer *et al.*, 2005).

Heavy metals can form reversible complexes with organic ligands during the chelation process. For example, lead may be concentrated as a complex in bile. Proteins such as metallothionein serve as transport molecules for metals (Hammond and Beliles, 1980). This scenario may alter the availability and delivery of metals to specific organs. On the other hand, certain toxic metals can accumulate in definite tissue locations. For instance, bone which can store high concentrations of lead can result in distribution to plasma protein or skin and hair. Susceptibility to dermal absorption of metals may be increased when the metal is organically bound, such as

methyl mercury or tetraethyl lead. One such study indicated that the dermal symptoms of inorganic, aryl and methoxy ethyl forms of mercury in cattle include skin pustules, ulcers, depilation (starting at the root of tail) and skin keratinization. Animals with severe skin damage are severely ill. The febrile response and skin color changes occurring in mercury poisoning can easily be confused with hog cholera and erysipelas. At the start of clinical syndrome, mercury poisoning in pigs also resembles the early skin reddening and abnormal gait resulting in organic arsenic poisoning (Osweiler *et al.*, 1985b).

Hair of animals may be the most common site of metal depositions since hair has a chemical affinity for heavy metals like arsenic, lead, thallium, selenium, bismuth and mercury. These metals have the potential to react with sulfhydryl groups of amino acids, particularly cysteine, in the follicular proteins and incorporated into the keratin. Because of the relative ease of getting hair samples, concentrations of metals in hair may be used as a biomarker for risk assessment surveys to determine the chronic heavy metal exposure in animals.

Forage crops grown on seleniferous soils contain sufficient amounts of selenium to cause poisoning in domestic animals. Selenium may cause acute and chronic poisoning in all animals, especially cattle, sheep, horses, swine, chicken and dogs. A loss of hair/wool, deformation and sloughing of the hoof are seen in cattle, sheep and horses that were poisoned chronically with selenium. This condition is commonly known as alkali disease; a misnomer (Osweiler *et al.*, 1985b). Chronic selenium (Se) toxicosis has been diagnosed in pigs with loss of hair, necrotic areas in the skin and lesions of the coronary band and hooves. The cause of this intoxication was the addition of the calculated amounts of sodium selenite directly to the feedstuff instead to mineral premix (Mihailovic *et al.*, 1992). In one occurrence of arsenic poisoning in cattle, arsenic in the hair of affected survivors was assayed at 0.8–3.40 ppm versus 0.09–0.10 ppm in randomly selected control samples (Riviere *et al.*, 1981). Inorganic tin salts are poorly absorbed and rapidly excreted in the feces; as a result they have a low toxicity. The main results of inorganic tin toxicity are skin and eye irritation; cholangitis of the lower biliary tract, and later hepatotoxicity; and neurotoxicity (Winship, 1988). Similarly, considerable skin changes in the form of scaliness on the dorsum of the neck and sloughing of the epidermis over neck, withers, ears, briskets, shoulders, back and tail were observed in beef calves after systemic administration of iodine. A slight degree of hair loss was also reported (Osweiler *et al.*, 1985b).

Chromium is an essential trace element required for normal protein, fat and carbohydrate metabolism. It also helps in energy production and increasing lean body mass. A unique form of bioavailable chromium is

niacin-bound chromium (NBC) that is used to promote a healthy lipid profile. The primary skin irritation test with NBC on New Zealand albino rabbits indicated that NBC was slightly irritating (Shara *et al.*, 2005).

Compounds other than metals can also produce dermal irritation on systemic administration. Oral administration of benzo[a]pyrene (PAH) caused the formation of DNA adducts in the skin (Baudouin *et al.*, 2002). The ingestion of hexachlorobenzene (VOC) in the rat leads to the formation of precancerous lesions in the skin and lungs (Michielsen *et al.*, 1999). The high doses of pyrethrins (insecticides) fed to rats can induce benign skin lesions (USEPA, 1995). Polybrominated biphenyls were used as fire retardant in many parts of the world. On accidental ingestion of this chemical with contaminated feed or by licking the contaminated wood, animals with alopecia and thickened skin over the thorax, neck and shoulder had been noted. Systemic exposure of ruminants and sheep to thiocarbamate (herbicide) can induce alopecia (Osweiler *et al.*, 1985b). Severe dermatitis over the ventral portion of the abdomen and inner surfaces of the limbs was developed in pigs that were given adriamycin (a systemic antibiotic) intravenously (Van Vleet *et al.*, 1979).

## ASSESSMENT METHODS

*In vivo* testing of certain chemicals for their irritating or sensitizing potentials and assessment of their dermal uptake are other sources of skin toxicity in experimental animals. Animal welfare regulations mandate the careful monitoring of dermal irritation and toxicity studies due to the potential for causing pain and skin damage resulting from cutaneously applied materials. In the U.S., the care and use of rabbits, guinea pigs, minipigs, dogs and non-human primates are regulated by the U.S. Department of Agriculture under the Animal Welfare Act (AWA, amended, 1985). Rats and mice are not included in this act, yet most institutions use these animals under similar internal standards for these species. According to this act skin irritancy testing is a procedure which can cause slight pain in the animal. Severe erythema, erosions, ulcers, abscesses and necrosis are the painful skin reactions produced in response to topical application of chemicals. The degree of skin toxicity in experimental animals varies with response to acute, subchronic or chronic dermal irritation studies.

Among assessment methods capable of causing dermal toxicity, cutaneous microdialysis, tape stripping and skin surface biopsies are the major *in vivo* models used to assess the dermal uptake of topically applied toxicants. Microdialysis is a promising technique for determination of *in vivo* dermal absorption (Simonsen *et al.*, 2004).

This technique consists of a semipermeable membrane forming a thin hollow tube that functionally resembles a blood vessel. The microdialysis probe is implanted in the dermis of the skin via a guide cannula. This technique is minimally invasive, and produces a minor trauma during insertion of the guide cannula for the implantation of the microdialysis probe; although this trauma is reversible (Groth and Serup, 1998) this can damage the skin considerably in sensitive animals. After the insertion of probe, an equilibration period of minimum 90 and 30 min in human and rat skin, respectively, is necessary to allow the effects of trauma to diminish (Groth, 1996). Tape stripping is suitable for studying the penetration of topically applied chemicals into the SC. This is composed of serial stripping of SC with the help of common adhesive tapes. This technique is invasive to the minimal extent and frequently used to study the reservoir effect of the SC for topically applied constituents and the assessment of their *in vivo* percutaneous penetration effects (Muhammad and Riviere, 2006). Another minimally invasive technique is skin surface biopsies. With the help of this technique, it is possible to track the permeation of a compound through the SC by taking consecutive biopsies in the same area (Dykes *et al.*, 1997).

## Blood and bone marrow toxicity

Mary B. Nabity and Shashi K. Ramaiah

### INTRODUCTION

Hematotoxicology is the study of adverse effects of drugs, non-therapeutic chemicals and other agents in our environment on blood and blood forming tissues such as bone marrow. Assessment of blood and bone marrow in veterinary toxicology is important since chemicals and drugs can significantly affect the cellular and humoral components of the blood. The hematopoietic system is unique and serves as a “cornerstone” to one’s understanding of the toxicology of blood and bone marrow. Hematopoietic cells are the most dynamic, proliferative and mitotically active cells in an animal. In humans, mature blood cell production is estimated at 1.5 million cells per second (Car, 2010). Therefore, toxicity to circulating blood cells or their precursors may be very serious and can result in life-threatening anemia, hemorrhage or profound infections.

Bone marrow is a common target for a variety of chemotherapeutic agents in animals and humans, some of which can result in total marrow aplasia (Lund, 2000). Many other drugs can also negatively impact blood components; therefore, the evaluation of blood and bone marrow in preclinical drug development is required by many regulatory agencies when assessing the safety and efficacy of test compounds (Bolliger, 2004). Because blood and bone marrow can be relatively easily assessed, sequential or parallel monitoring of blood and bone marrow has become a standard component of hematotoxicity screening by the pharmaceutical industry as well as in the clinics. This chapter is intended to provide a basic introduction to blood and bone marrow as well as illustrate some toxicant-induced changes. Information provided in this chapter should serve as an important and

accessible tool for understanding basic concepts, and for monitoring and characterizing toxic responses of the blood and bone marrow.

### BONE MARROW

Hematopoiesis normally occurs in the bone marrow of both flat bones and long bones, and in mice it can also occur normally in the spleen (Gasper, 2000). Blood supply to the marrow is mainly provided by nutrient arteries that penetrate cortical bone, particularly at the mid-shaft of long bones. These arteries extend along the longitudinal axis of the bone and send off radial branches throughout the marrow. These branches terminate at the periphery of the marrow cavity and connect with venous vessels. Venous or vascular sinuses of marrow are thin-walled vessels with abundant anastomoses, and they carry blood back to central veins. Marrow lacks lymphatic vessels. Nerves in the marrow are vasomotor and found in association with the vasculature.

The hematopoietic compartment of the marrow consists of irregular and anastomosing cords that lie between vascular sinuses (Bloom, 1997). Blood cells are produced in the hematopoietic compartment of the marrow and reach the circulation by migrating through the vascular sinus endothelium. Marrow fat cells represent a mechanical buffer that occupy or release space within the medullary cavity in response to changing demands for hematopoiesis. Adventitial reticular cells provide structural support for hematopoietic colonies. The extent of marrow fat and adventitial coverage of vascular sinuses varies inversely with the degree of hematopoiesis and the

rate of cell delivery to the bloodstream. Thus, the amount of fat in the marrow increases with age (Bloom, 1997).

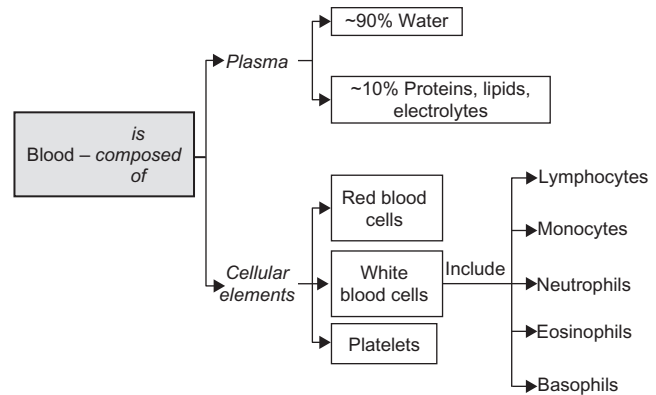

## HEMATOPOIETIC STEM CELLS

A pluripotent stem cell that can produce all blood cell types, including lymphocytes, is said to be totipotent. Most totipotent stem cells in adults are not in the cell cycle, but are quiescent. Totipotent stem cells account for less than 0.2% of the total hematopoietic cells in the marrow. In adult mammals, most of these cells are lodged in the bone marrow, but small numbers enter, circulate and return from blood. Low numbers are also present in the spleen. Totipotent hematopoietic stem cells produce pluripotent myeloid and lymphoid stem cells. Pluripotent stem cells give rise to progenitor cells which are capable of forming colonies in marrow culture, like stem cells, but lack long-term self-renewal capacity and are generally more restricted in their differentiation (Meyer and Harvey, 1998). Many progenitor cells are in the active cell cycle. They are capable of producing progeny (blast cells) that can be recognized morphologically. These resultant blast cells are classified as “precursor cells.”

The pluripotent myeloid stem cells give rise to a series of progressively more differentiated progenitor cells that support the production of all nonlymphoid cells. When grown in an *in vitro* cell culture assay, each colony of cells represents one progenitor cell and is referred to as a colony-forming unit (CFU). With time, a few large colonies may appear in culture, originating from a more immature progenitor cell, and these are referred to as burst-forming units (BFUs) (Meyer and Harvey, 1998). Both the local marrow microenvironment and systemic humoral factors influence hematopoiesis to stimulate or suppress the proliferation and differentiation of single or multiple cell lineages. In general, multi-colony growth factors such as interleukin-3 (IL-3) stimulate early progenitor cells, whereas single colony factors such as erythropoietin (EPO) and granulocyte-macrophage colony stimulating factor (GM-CSF) act on more differentiated progenitor cells such as erythroid and granulocyte-macrophage progenitor cells, respectively.

## BLOOD COMPONENTS

Blood consists of cells and protein-rich plasma (Figure 22.1). Blood cells include erythrocytes (red blood cells), platelets (usually called thrombocytes in nonmammalian species) and leukocytes (white blood cells). The leukocytes in most vertebrates are classified

**FIGURE 22.1** Blood components. The blood consists of the fluid-rich plasma component and the cellular component consisting of red and white blood cells. The white blood cells are composed of neutrophils, basophils, eosinophils, monocytes and lymphocytes. See text for details on morphology of these cells.

as granulocytes (neutrophils, eosinophils and basophils) or mononuclear cells (monocytes and lymphocytes). Freshly drawn blood rapidly clots, but clotting can be prevented by the addition of an anticoagulant, thereby allowing for assessment of blood cell morphology on a properly prepared blood film (Figures 22.2 and 22.3) and separation of the plasma and cellular components into three distinct layers after centrifugation (Andrews, 1998; Meyer and Harvey, 1998). The lowest layer is red since it consists mostly of erythrocytes, and the percent volume of this layer with respect to the total blood volume determines the packed cell volume (PCV) or hematocrit (HCT), which is normally approximately 35–45% in most species. The thin, gray-white middle layer immediately above the erythrocytes is the buffy coat, and it accounts for approximately 1% of the blood volume. The buffy coat contains platelets and leukocytes, but immature erythrocytes may also be present in this layer. The top (fluid) layer is the plasma. Plasma contains 91–92% water and 8–9% solutes such as proteins, lipids and electrolytes (Figure 22.1). A variety of homeostatic mechanisms ensure that plasma volume, pH and constituents are tightly regulated. When clotting of blood occurs, fibrinogen and many coagulation factors are depleted from the fluid component. The resulting fluid is called serum (Andrews, 1998; Meyer and Harvey, 1998).

### Erythrocyte, leukocyte and platelet formation

Immature blood cell precursors are generally larger than mature forms, and they have a large euchromatic nucleus resulting in a high nuclear to cytoplasmic (N:C) ratio. As blood cells mature, their size and N:C ratio gradually decrease.

**FIGURE 22.2** (A) Examples of erythroid precursors and granulocytic precursors (arrowheads) in the bone marrow of a dog. Diff-quick stain. Early erythroid precursors (arrow heads), late erythroid precursors (solid arrows) and granulocytic precursors (dotted arrows) are shown. (B) A mature megakaryocyte in the bone marrow of a dog is shown in the center of the picture. Erythroid and myeloid precursors are also noted (arrows). Modified Wright's stain.

**FIGURE 22.3** Normal and some abnormal erythrocyte and leukocyte morphologies. (A) Two large basophilic polychromatophilic erythrocytes or reticulocytes (small solid arrow) are present in the blood from a dog with IMHA. A normal neutrophil (dotted arrow), a metarubricyte and a lymphocyte (long arrow) are also present. Modified Wright's stain. (B) Heinz bodies in the blood from a cat appearing as pale "spots" within erythrocytes with a modified Wright's stain. (C) Eosinophil with round granules in the blood from a dog. Modified Wright's stain. (D) Basophil (arrow) and neutrophil in the blood from a dog. Modified Wright's stain. (E) Monocyte (arrow) and neutrophil in the blood from a dog. Modified Wright's stain. (F) Toxic neutrophils in the blood from a cat demonstrating Döhle bodies, cytoplasmic vacuolation and basophilia. A platelet (arrow) is also identified in the field. Modified Wright's stain.

### Erythropoiesis

Erythropoiesis is the process by which committed hematopoietic progenitor cells develop into anucleate, hemoglobin-containing, biconcave discs (in mammals) called

erythrocytes. EPO regulates this process. Rubriblasts, the first recognizable erythroid precursor, undergo approximately four cell divisions to generate the last nucleated stage, the metarubricyte (Figure 22.2a). However, intracellular hemoglobin concentration is an important

factor in determining the number of cell divisions a cell undergoes to produce this stage (Car, 2000). With the extrusion of the nucleus, the resulting immature erythrocyte is termed a reticulocyte. The reticulocyte persists for about 2 days after release into the circulation before maturation into a mature erythrocyte. Under normal situations, few reticulocytes are seen in peripheral blood, but some strains of rodents may normally have up to 10% circulating reticulocytes (Fernandez and Grindem, 2000). The lifespan of mature erythrocytes ranges from 43 to 145 days, depending on the species (Christian, 2010).

### **Granulopoiesis**

Granulopoiesis is the process by which committed hematopoietic progenitor cells develop into granulocytes under the influence of various growth factors and cytokines. Neutrophils and monocytes are derived from a common progenitor, the colony-forming unit granulocyte-macrophage (CFU-GM), whereas eosinophils and basophils are derived from different progenitor cells (CFU-Eo and CFU-Ba, respectively). The first recognizable granulocytic precursor is the myeloblast. Early granulocyte precursors (myeloblast and promyelocyte) appear similar between the various granulocytic cell lines until the myelocyte stage, which is the final stage capable of cell division. At this stage, they develop characteristic secondary lineage-specific granules (neutrophilic, eosinophilic or basophilic). During the next stage (the metamyelocyte), the nucleus of the granulocyte indents and lobulation begins, eventually producing the characteristic polymorphonuclear appearance (Figure 22.2a, b) (Gasper, 2000; Smith, 2000).

### **Platelet formation**

The megakaryocyte is a polyploidy cell with cytoplasm that becomes increasingly granular with maturity (Figure 22.2). Platelets are derived from the megakaryocyte cytoplasm. The mechanism by which platelets are released from their parent cell is unclear, but it appears to be by cytoplasmic fragmentation. This process may take place in an extramedullary location (i.e., lung, spleen). The cytokine thrombopoietin is the major stimulus for megakaryocyte proliferation, platelet production and differentiation from a common progenitor cell, the CFU-GEMM (Andrews, 1998). If unconsumed, the platelet lifespan ranges from 3 to 10 days depending on the species (Weiss, 2000).

## **Erythrocyte, leukocyte and platelet biology**

### **Erythrocyte**

#### *Erythrocyte function*

The function of red blood cells is to transport oxygen to tissues. Decreased hemoglobin lowers oxygen delivery

to tissues. This results in increased EPO secretion from the kidney and subsequent stimulation of erythrocyte production.

#### *Morphology of erythrocytes*

Mature erythrocytes are anucleate biconcave discs. The degree of concavity varies among the domestic species, and typical biconcave erythrocytes, as indicated by central pallor, are present in dogs, cows, sheep, rats and mice. The concavity and resulting pallor are not prominent in horses and cats. In most species, an increase in central pallor indicates decreased hemoglobin content. Slight anisocytosis (variation in size) of erythrocytes is common in most animal species, and poikilocytosis (variation in shape) is normally present on smears made from the blood of goats and some species of deer. Erythrocytes may adhere to each other and form long chains resembling stacks of coins. This phenomenon, called rouleaux formation, is normally prominent in horses and cats, intermediate in dogs and pigs, and rare in ruminants. Rouleaux formation is often increased in inflammatory states. Reticulocytes are immature anucleate erythrocytes that appear large and polychromatophilic (bluish red color) on Wright's stained blood films (Figure 22.3a). Reticulocytes contain residual ribonucleic acid (RNA) (ribosomes and polyribosomes) and mitochondria, which aggregate into a reticular mesh when stained with vital stains (e.g., new methylene blue) but not with Romanowsky-type stains. Quantitation of reticulocytes in circulation is used as an index of bone marrow erythropoietic response since circulating reticulocytes should be numerous when the marrow is responding to an increased demand for erythrocytes. Heinz bodies result from the oxidation and aggregation of hemoglobin and are therefore an indication of oxidative damage (Meyer and Harvey, 1998; Harvey, 2001). They appear as pale red inclusions within or along the edge of the cytoplasm using Romanowsky-type stains, but they stain light to medium blue with reticulocyte stains (Figure 22.3b). Similar to diagnostic medicine, the above alterations in RBC shape or appearance are only a portion of those that may be seen in clinical patients or in preclinical safety studies during drug development. Readers are referred to other sources for a more complete list of RBC morphologies and their significance (Harvey, 2001).

#### *Heme synthesis*

The synthesis of heme involves a series of reactions that starts in the cytoplasm and mitochondria of the rubriblast, the earliest identifiable precursor of erythrocytes. Heme synthesis begins with the vitamin B<sub>6</sub>-dependent condensation of succinyl-CoA and glycine to form delta aminolevulinic acid (ALA). ALA then condenses to form

a pyrrole, and this step is inhibited by lead. Porphyrin rings are then generated and a final step incorporates an iron atom. Ferrochelatase, also inhibited by lead, catalyzes this incorporation of the ferrous iron into the tetrapyrrole protoporphyrin IX in the mitochondria (Meyer and Harvey, 1998; Kaneko, 2000).

#### *Iron metabolism*

Iron is primarily obtained from dietary sources where it is absorbed from the gut and transported as a complex with transferrin to the marrow. Iron is transferred to red blood cell precursors by receptor-mediated endocytosis. Iron stores are usually assessed by staining the marrow with Prussian blue or by measuring serum ferritin (Jain, 1993; Harvey, 1997). Cats normally lack stainable iron in their marrow (Nadrew *et al.*, 1994). Iron deficiency may result in several clinical features, such as anemia, increased erythrocyte central pallor and abnormal shapes of the red cells.

#### *Red blood cell energy requirements and hemoglobin breakdown*

The energy required by erythrocytes is especially important for the maintenance of a reduction potential to prevent hemoglobin oxidation. In mature red blood cells there are no mitochondria, therefore, the glycolytic pathway and pentose phosphate pathway are the main sources of ATP and NADPH that provide energy to prevent oxidative damage, e.g., via reduced glutathione (GSH). Aged or damaged red blood cells are removed from circulation by macrophages of the reticuloendothelial system in the spleen, liver and marrow. In the macrophage, hemoglobin is catabolized to globin and heme. The amino acids from globin re-enter the protein synthesis pool. Heme is degraded to biliverdin then to bilirubin and excreted in the urine and bile (Jain, 1993).

### **Leukocyte**

#### *Leukocyte biology*

Neutrophils primarily function in inflammatory responses and bacterial killing. With an increased demand for neutrophils, neutrophil production is up-regulated by growth factors and proinflammatory cytokines. Mature circulating neutrophils are present either in the circulating pool or the marginal pool. Neutrophils in the marginal neutrophil pool are loosely bound to capillary endothelial cells. Several physiological factors such as epinephrine and corticosteroids due to excitement and stress cause demargination of neutrophils and result in neutrophilia (Babior and Golde, 1995).

#### *Morphology of leukocytes*

Total leukocyte count refers to the total absolute count of circulating neutrophils, eosinophils, basophils,

monocytes and lymphocytes, and this number varies among different animal species. The differential leukocyte count refers to the percentage of each leukocyte population in peripheral blood and should be performed by counting and differentiating a minimum of 200 cells on a stained blood film. Granulocytes are classified according to the staining characteristics of their specific (or secondary) cytoplasmic granules. Eosinophils have pronounced acidophilic granules, basophils possess distinct basophilic granules and neutrophils have small, neutral, usually indistinct granules. The proportion of different populations of leukocytes also varies among animal species. For example, neutrophils predominate in dogs and cats, whereas they only slightly outnumber lymphocytes in horses. In ruminants and laboratory animals (rats and mice), lymphocytes predominate. The morphology of the various populations of leukocytes is fairly similar among animal species (Duncan *et al.*, 1994).

#### *Neutrophils*

Once released from the bone marrow into the peripheral blood, neutrophils circulate for 6–14h before migrating into tissues, where they survive for 1–4 days (Smith, 2000). Neutrophils account for approximately 40–70% of the total leukocyte count depending on the animal species. Mature neutrophils have a segmented nucleus with three to five lobes joined by thin strands, and they contain heterochromatic (clumped) chromatin (Figure 22.3). Occasionally, a nuclear appendage, an extra chromatin lobe resembling a drumstick, is present in neutrophils of female animals and is commonly known as the Barr body. The neutrophil cytoplasm is pale and contains a moderate number of fine pink or pale granules, depending on the animal species. Neutrophils from veterinary species are known to contain at least two types of cytoplasmic granules: azurophilic (primary) and specific (secondary) granules. In birds, reptiles and some fish, the equivalent of a neutrophil is called a heterophil, and it contains large, reddish cytoplasmic granules. The neutrophils in rabbits, guinea pigs and hamsters also contain similar-appearing granules and are therefore often referred to as heterophils. Rat and mouse granulocytes are unique in that their granulocytic precursors can develop “ring forms” in which a small “hole” is present in the center of the nucleus. These ring forms are also called “stab cells.” Ring forms are seen in neutrophil and eosinophil precursors but not in basophil precursors (Bolliger, 2004).

In healthy animals, only mature neutrophils are present in circulation. Immature neutrophils, as indicated by a decrease in nuclear segmentation, are normally restricted to the bone marrow but may be released into the blood during a granulocytic response to a disease process. Neutrophil toxicity is seen secondary to an

overwhelming demand for neutrophils, resulting in maturational defects. Neutrophil toxicity is characterized by increased cytoplasmic basophilia, foamy vacuolation and Döhle bodies (amorphous blue-gray cytoplasmic inclusions) (Figure 22.3f) (Jain, 1993; Meyer and Harvey, 1998).

### *Eosinophils*

Eosinophils are seen in low numbers, and they contain a polymorphic nucleus that is less condensed and less segmented than that of neutrophils. As eosinophils mature in the bone marrow, most primary azurophilic granules disappear or transform into specific granules. In mature cells, the pale blue cytoplasm contains mostly specific eosinophilic (red/pink) granules that are loosely packed in the cell (Figure 22.3c). The size, shape, number and staining characteristics of eosinophils vary among different animal species (Young, 2000).

### *Basophils*

Few basophils are present in normal blood. They have a segmented or irregularly shaped, often string-like, heterochromatic nucleus. The nuclear segmentation, as in eosinophils, is less pronounced in basophils. Cytoplasmic granules are metachromatic and prominent, and they stain reddish violet (Figure 22.3d). The size, number and staining reaction of granules vary among animal species. Basophils have some morphologic resemblance to mast cells, which are widely distributed in connective tissues and only rarely observed in blood. Compared to basophils, mast cells are bigger with a round nucleus and more numerous cytoplasmic granules (Scott and Stockham, 2000).

### *Monocytes*

The monocyte is generally the largest blood leukocyte and accounts for 3–8% of the total leukocyte count. Monocytes are precursors of tissue macrophages, and their nucleus can vary from bean shaped to convoluted. Their cytoplasm is abundant, blue-gray, and often appears foamy or vacuolated with a few large vacuoles (Figure 22.3e). Monocytes often have many fine or indistinct azurophilic cytoplasmic granules (Bienzle, 2000).

### *Lymphocytes*

Lymphocytes account for 20–40% of the total leukocyte count in dogs, cats and horses; 60–70% in ruminants, mice and rats; and 50–60% in pigs. Morphologically, lymphocytes are classified as small, medium and large depending on their size. The size, shape and staining characteristics of lymphocytes vary among and within animal species. Dogs and cats have mostly small circulating lymphocytes (Figure 22.3a). Both small and large lymphocytes are present in cows, sheep, goats and

rodents. In cows, large lymphocytes occasionally may have vacuolated cytoplasm and a few large azurophilic granules (Meyer and Harvey, 1998).

## **Platelet biology**

### *Platelet function*

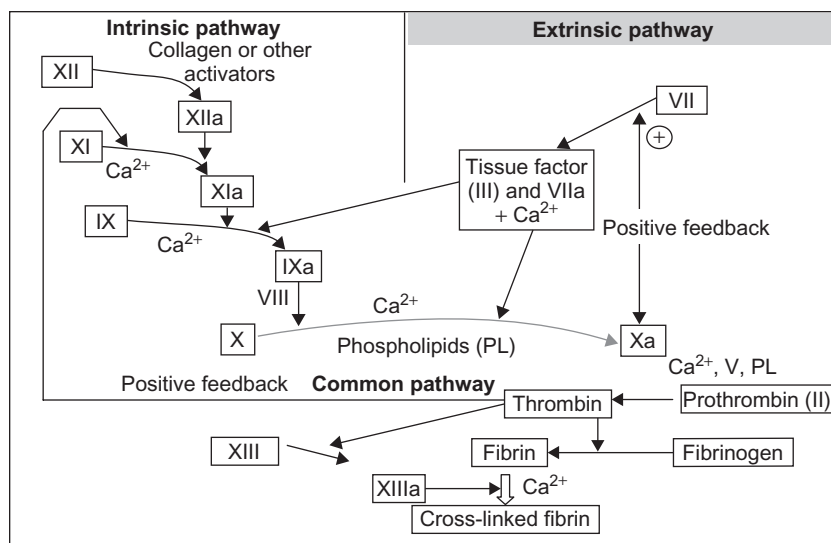

Platelets function largely in primary hemostasis. Initially, platelets adhere to the endothelium of damaged blood vessels, undergo shape changes and release proteins that cause the aggregation of more platelets to form a platelet plug and help stimulate the coagulation pathway (Figure 22.4). Platelets play a major role in secondary hemostasis as well. For example, platelets provide a surface for the assembly of several enzyme complexes that form during the process of coagulation, provide coagulation factor V and participate in the activation of factor X. Collagen stimulates platelet aggregation and platelet adhesion. Adhesion occurs between the platelet membrane and subendothelial components (collagen and fibronectin) via von Willebrand factor and glycoprotein receptors. ADP and thromboxane A<sub>2</sub> are secreted by adherent platelets and released from damaged tissue and erythrocytes, and these contribute to early platelet aggregation. Fibrinogen plays a major role in the coagulation cascade as well as in platelet aggregation (Bauer and Rosenberg, 1995).

### *Morphology of platelets*

Platelets generally vary in size and shape and are smaller than red blood cells. In stained blood films, platelets are discoid, spherical or elongated and may appear individually (Figure 22.3f) or in small to large aggregates. They are anucleate in mammals. A direct platelet count is performed on blood samples using a hematology analyzer. A subjective screening of platelet numbers (normal, increased or decreased) can also be made from their relative number on stained blood films. The terms platelet and thrombocyte are used interchangeably, although the term thrombocyte is preferentially used to describe nucleated platelets in fish, reptiles, amphibians and birds (Boudreaux, 1996; Meyer and Harvey, 1998).

### *Hemostasis*

Hemostasis occurs when there is a balance between continuous activation of the coagulation cascade and removal of the end product of coagulation, fibrin, by fibrinolysis. As mentioned previously, hemostasis can be categorized into primary hemostasis, with the formation of a platelet plug and secondary hemostasis, culminating in a fibrin clot. There are three major pathways involved in secondary hemostasis: the extrinsic, intrinsic and common pathways (Figure 22.4). In the extrinsic

**FIGURE 22.4** A diagram of the coagulation cascade consisting of intrinsic, extrinsic and common pathways. Coagulation is an enzymatic process involving the conversion of inactive enzymes to active forms resulting in amplification of the process. The final product of these pathways is the formation of cross-linked fibrin. PL is phospholipid of platelets. Roman numerals refer to the coagulation factors with these numbers. "a" following a Roman numeral indicates "active enzyme." For details, see section on platelet biology.

pathway, the initiating stimulus is the release of tissue factor from damaged endothelium and other tissues. The intrinsic pathway can be initiated by either the extrinsic pathway or contact with negatively charged surfaces such as damaged endothelium. Both the extrinsic and intrinsic pathways stimulate a series of steps, many of which are shared in the common pathway, resulting in the production of thrombin and eventually a stable fibrin clot. Calcium is a requirement in many of these steps, and phospholipids (provided by platelets) are also required for enzyme complex activity. The majority of the coagulation factors are produced by the liver. Some factors such as Factors II, VII, IX and X are dependent on vitamin K, which is obtained from the diet and produced by intestinal bacteria. Breakdown of the fibrin clot is achieved by activating plasminogen to plasmin, which degrades fibrin. Tests commonly used to measure secondary hemostasis include prothrombin time (PT), partial thromboplastin time (PTT) and activated coagulation time (ACT) (Table 22.1) (Bauer and Rosenberg, 1995; Boudreaux *et al.*, 1996).

## BIOCHEMICAL BASIS OF HEMATOPOIETIC TOXICITY

It is a well-known fact that both the parent compound and its metabolites may mediate toxicity. Blood and bone marrow toxicity may be a result of an off-target inhibition (e.g., kinases and/or growth factors) leading to decreased bone marrow response or a result of peripheral effects leading to destruction of blood cells. Alterations in the blood and bone marrow cells may also be an anticipated pharmacologic event during preclinical

drug development (Meyer *et al.*, 2010). Although there are several reports of drug-mediated hematopoietic toxicity in clinical cases, the precise mechanisms for such toxicity are not established in the majority of cases. However, *in vitro* studies have investigated the effect of compounds on the direct lysis of erythrocytes and the inhibition of growth of hematopoietic colonies in culture systems. Although mechanistically important, these results may only be extrapolated to the *in vivo* situation where the compound under test is not modified by host metabolic processes. Classic examples of a discrepancy between *in vitro* and *in vivo* studies include chloramphenicol-induced myelosuppression and 2-butoxyethanol-induced hemolysis (Turton *et al.*, 2002a, b; Corley *et al.*, 2005). The myelosuppressive activity of chloramphenicol is usually ascribed to the parent compound, but the nitroso metabolite of chloramphenicol shows a far greater inhibitory effect in mouse hematopoietic culture assays. In addition, there is considerable variation in the susceptibility of cells from different mouse strains to the nitroso metabolite. In man, nitroso-chloramphenicol has not been identified as an *in vivo* metabolite of chloramphenicol, further hampering any extrapolation from *in vitro* toxicity studies to the clinical situation (Jimenez *et al.*, 1987; Turton *et al.*, 2002b). The cleaning agent 2-butoxyethanol (2-BE) is reported to be inactive in the *in vitro* hemolysis test in rats, while oral administration in this species produces a hemolytic anemia. However, the major metabolite of 2-BE, butoxyacetic acid, produces marked swelling and lysis of erythrocytes *in vitro* (Corley *et al.*, 2005).

Another major mechanism of toxicity seen with many compounds involves the formation of reactive oxygen species (ROS), including superoxide anion, hydrogen peroxide and hydroxyl radical. ROS are capable of reacting with cellular proteins, lipids and other molecules

TABLE 22.1 Commonly used tests to detect toxic effects on blood and bone marrow in clinical and preclinical toxicology

Name of test	Usefulness	Comments
<i>Complete blood count (CBC):</i> PCV, MCV, MCHC, WBC count, differential leukocyte count, platelet count	Routine blood analysis for screening effect of toxic chemicals	Modern blood analyzers report these erythrocyte indices as part of a full blood count, and manual evaluation may be necessary to confirm findings and detect unusual red and white cell abnormalities
<i>Hemolysis testing</i> (e.g., osmotic fragility test and Heinz bodies)	To confirm if hemolysis is responsible for lowered red blood cell count	Look for Heinz bodies, methemoglobinemia and eccentrocytes to detect oxidant-induced changes; spherocytes indicate immune-mediated destruction
<i>Hemostatic tests</i> (e.g., platelet numbers, PT, PTT, ACT, bleeding time)	To detect abnormalities of coagulation in the extrinsic (PT) and intrinsic (PTT, ACT) path-ways and platelet function (bleeding time)	Special tests like D-dimer assay, antithrombin, platelet function tests and individual factor assays are available in some university and commercial research laboratories
<i>Special blood tests</i> Reticulocyte count, Coombs, platelet associated immunoglobulin G (PAIgG)	These tests are based on the routine CBC findings and are considered “problem driven” tests	Reticulocyte evaluation will determine bone marrow response to anemia; Coombs and PAIgG tests may indicate an immune-mediated component in anemia and thrombocytopenia
<i>Bone marrow cytology (evaluate myeloid: erythroid ratio)</i>	Confirm blood findings and to evaluate marrow function	This is an elaborate and time-consuming procedure. Cytochemical staining can be performed to differentiate abnormal cells in cases of leukemia
<i>In vitro</i> stem cell assays using clonogenic (CFU-E, CFU-GM, CFU-GEMM) assays	Possible to examine effects on the myeloid, erythroid and megakaryocytic lineages in a fashion where concentration of the chemical and duration of exposure are tightly controlled	<i>In vitro</i> clonogenic assays have proven useful in understanding mechanisms of toxicity and in formulating strategies for treatment

leading to changes in their structure and subsequent cellular damage. Despite numerous cellular defense mechanisms such as antioxidant enzymes and low molecular weight antioxidants such as GSH, hemolysis may result if these mechanisms are overwhelmed in red blood cells. Many oxidants cause hemolysis by this mechanism (e.g., acetanilide, naphthalene, phenol; [Table 22.2](#)). One such compound that has been extensively tested is microcystin-LR, which significantly increases oxidative stress causing lipid peroxidation, changes in membrane fluidity, transformations of cell shape and hemolysis. A significant dose- and time-dependent increase in lipid peroxidation products was found in red blood cells treated with microcystin-LR when compared with untreated controls ([Sicinska et al., 2006](#)).

Non-selective kinase inhibitors can be potential bone marrow suppressants due to inhibition of key cytokines responsible for hematopoiesis. Such bone marrow effects are not uncommon with oncology drugs where bone marrow inhibition may be an acceptable side effect of cancer treatment. Ironically, chemotherapeutic and other toxic agents, particularly alkylating agents, may result in leukemia, which is likely linked to cytogenetic abnormalities, especially with the loss of part or all of a chromosome. The frequency of cytogenetic abnormalities in human patients who develop dysplastic syndrome or acute leukemia after treatment with alkylating or other antineoplastic agents ranges from 67 to 95%. However, there are other forms of leukemia that have weak correlations with exposure to alkylating agents ([Bloom and Brandt, 1997](#)).

TOXICITY-INDUCED ALTERATIONS OF  
HEMATOPOIETIC ELEMENTS

The following section discusses several mechanisms and specific causes of hematopoietic alterations. It is important to remember, however, that preanalytical factors (e.g., age, diet, fasting collection, sample handling) can have significant effects on hematological parameters and such variations should be minimized in controlled studies. A partial list of drugs/chemicals shown to have toxic effects on blood and bone marrow is included in [Table 22.2](#).

Myelosuppression

Bone marrow suppression may result from direct damage to cell precursors as well as from alterations in the cytokine profile secondary to the drug. Suppression is a widely recognized side effect of chemotherapeutic/antineoplastic agents, primarily due to the high mitotic rate of this tissue. All cell lines may be affected resulting in granulocytopenia, thrombocytopenia and/or anemia. The changes are usually dose related and reversible after withdrawal of the drug/test compound ([Turton et al., 2006](#)). The mechanisms involved in such dose-dependent myelosuppression are related to inhibitory effects on primitive cells in the marrow such as BFU-E and CFU-GM ([Deldar, 1994](#)). The inhibition of these primitive cells will manifest as erythroid hypoplasia and neutropenia, respectively,

TABLE 22.2 Few examples of drugs and chemicals associated with a variety of toxic effects and their likely mechanism of action

Drug/chemical	Effect	Mechanism of action
Chloramphenicol, sulfonamide, diclofenac, mycotoxins	Bone marrow aplasia	Unknown
Trimethoprim-sulfadiazine, cephalosporin, phenobarbital	Pancytopenia	Possibly immune-mediated destruction of stem cells
Benzene	Bone marrow aplasia	Damaged marrow microenvironment
Chlorinated hydrocarbons	Bone marrow aplasia	Stem and progenitor cell damage
Estrogen	Anemia; bone marrow suppression	Stem cell damage and decreased EPO
Arsenic	Hemolytic anemia; dyserythropoiesis	Altered DNA synthesis
Amphotericin B, insulin, isoniazid, cisplatin, rifampicin, naproxen, sulfonamide	Immune-mediated hemolytic anemia (IMHA)	Antibody-mediated destruction of erythrocytes
Aniline, acetanilide, naphthalene, phenol, nitrobenzene, sulfanilamide	Oxidative stress-induced anemia	Oxidative damage to erythrocytes
Nitrites, nitrobenzenes, phenacetin, methylene blue	Toxic methemoglobinemia	Oxidation of red blood cell hemoglobin
Warfarin, cephalosporins	Bleeding	Inhibition of the carboxylation of vitamin K-dependent coagulation factors
Heparin, gentamycin, aspirin, acetazolamide, cephalixin, gold salts	Thrombocytopenia	Immune-mediated platelet destruction

and may be due to direct cytotoxicity, inhibition or blockage of specific growth factors, or interference with some fundamental process such as DNA replication. For example, EPO production has reportedly been suppressed by excess estrogen due either to exogenous administration or endogenous release as occurs with estrogen-secreting tumors (Thrall *et al.*, 2004). Other known bone marrow suppressants whose actions are dose dependent and reversible include aminopterin, a folic acid antagonist, and benzene (Table 22.2). Azidothymidine (AZT) used in the treatment of feline immunodeficiency virus and feline leukemia virus is another example of a drug that causes anemia primarily by bone marrow suppression. Ingestion of trichloroethylene is known to cause aplastic anemia in cattle. Other chemicals/drugs known to cause bone marrow suppression include chloramphenicol, meclofenamic acid, phenylbutazone, quinidine, trimethoprim-sulfadiazine, albendazole and fenbendazole (Manyan *et al.*, 1972). Chronic treatment with recombinant human erythropoietin (rhEPO) has also been shown to cause erythroid hypoplasia and nonregenerative anemia due to the production of anti-EPO antibodies. This effect is reversible over the course of 2–12 months after discontinuation of the drug (Langston *et al.*, 2003).

## Anemia

Anemia secondary to drugs or toxins may arise due to bone marrow suppression, hemorrhage or increased destruction. A mild anemia is a common feature in pre-clinical toxicology studies in which high doses of a drug or a chemical are administered. The anemia is usually

secondary to toxicity affecting other organ systems and is thought to be similar to anemia of inflammatory disease often seen in clinical cases. This finding is usually nonspecific and insignificant. Another common reason for mild anemia in toxicology studies is attributed to the combination of frequent blood sampling for toxicokinetic studies and the stress of repeated handling, especially in primates (Hall, 1992; Gossett, 2000). In the bone marrow, decreased red blood cell precursors can also be noted in toxicology studies concurrent to decreased food intake and loss of body weight (Reagan *et al.*, 2011). If prolonged, this could lead to anemia.

### Immune-mediated hemolytic anemia

Drug-induced immune-mediated hemolytic anemia (IMHA) in humans is thought to occur as a result of the following three mechanisms: formation of antibodies (IgG, IgM or IgA) to drug adhered to red cell membranes (hapten or neoantigen formation), binding of preformed drug-antibody complexes to the red cell membrane, or autoantibody formation. However, documented cases of drug-induced IMHA in animals are infrequent and most are probably related to hapten formation. Examples of IMHA caused by drugs in animals include penicillins and cephalosporins, which are known to cause anemia by a combination of immune-mediated hemolysis and bone marrow suppression. Levamisole is another drug suspected of inducing IMHA in dogs that are being treated for heartworm disease. Vaccination has also been implicated in cases that present with IMHA within short periods of time after vaccination. However, the precise mechanism for such a response due to vaccination is not known at present (Bloom *et al.*, 1988; Andrews, 1998; Gossett, 2000).

### *Oxidative or nonimmune hemolysis*

Exposure to oxidants results in the production of methemoglobin and/or large aggregates of oxidized, precipitated hemoglobin that are attached to the internal surface of erythrocyte membranes (Heinz bodies, Figure 22.3b). Eccentrocytes are also often formed with oxidative damage resulting from altered cytoplasmic-membrane adhesions. The attachment of Heinz bodies to the plasma membrane causes membrane rigidity with subsequent red blood cell lysis and anemia. Several oxidants are implicated in oxidative hemolysis caused by Heinz bodies. Examples in dogs and/or cats include methylene blue, onions, acetaminophen, phenazopyridine and propylene glycol, and phenothiazine in horses. Zinc-induced hemolytic anemia may occur due to ingestion of metallic hardware items, pennies and topical formulations containing zinc oxide. Sudden release of copper from accumulations in the liver of several species (particularly sheep) has been reported to cause Heinz bodies and an acute hemolytic crisis. Vitamin K and DL-methionine induce methemoglobinemia in multiple species, although Heinz bodies and anemia are not frequent (Houston and Myers, 1993; Schlesinger, 1995).

### *Basophilic stippling*

Basophilic stippling is usually seen in mature erythrocytes and is thought to be due to the presence of aggregates of ribosomes and polyribosomes. Basophilic stippling usually represents a regenerative response to anemia in ruminants and less commonly in other species. It may also be seen in lead poisoning, likely due to retention of RNA (Weiss, 2010). Siderotic inclusions (Pappenheimer bodies) in the red blood cells resemble basophilic stippling. Siderotic inclusions contain iron and may be seen after isoniazid therapy, lead toxicity, chloramphenicol and zinc toxicity.

### *Neutrophilia and neutropenia*

An elevated neutrophil count is often present in cases of bacterial infection and many inflammatory conditions, although initially a neutropenia may be detected. In addition, chemicals such as lead, mercury, phenacetin and pyridine may induce neutrophilia as a secondary response to tissue damage or hypersensitivity reactions. Neutrophilia is often seen in laboratory animals as a secondary event in neoplastic conditions or following hemorrhage. Increased neutrophil production and delivery to the circulation in response to inflammation may be the result of multiple signals including endotoxin, interleukins, interferons and cytokines (Anderson, 1993). Approximately 3–5 days are required for a significant increase in neutrophils to be observed peripherally due to increased bone marrow production (Duncan *et al.*,

1994). Neutropenias may be observed due to destruction of mature neutrophils, myeloid precursors or supporting cells. Neutropenia may also be secondary to attenuation of inflammation by a drug rather than suppression of granulopoiesis, as seen with a selective JAK inhibitor (Meyer *et al.*, 2010).

### *Eosinophilia, monocytosis and lymphocytosis*

Eosinophilia is seen in parasitic infections, dermatitis and occasionally in allergic reactions to drugs such as salicylates. Increased eosinophils may be seen in the peripheral blood and wall of the rat gut following the use of dietary expanders such as modified starches and sugars (sorbital, mannitol, lactose and polyethylene glycol). Eosinophilia has also been reported with excessive fluoride ingestion in rats (Andrews, 1998).

Monocytosis is often seen concomitant with neutrophilia and is usually a nonspecific finding of inflammation or stress. It is also seen acutely after trauma such as accidental gavage of the lung in rodents. Monocytosis has been described resulting from the administration of the antipsychotic drug chlorpromazine (Andrews, 1998).

Increased lymphocyte numbers may be present peripherally following immunization and with physiological excitement due to epinephrine (Meyer and Harvey, 1998).

### *Erythrocytosis and thrombocytosis*

Increased numbers of erythrocytes (erythrocytosis) seen in peripheral blood is usually a relative versus absolute increase, meaning that it usually does not represent a true increase in red cell mass. It is frequently associated with hemoconcentration/dehydration due to decreased food intake or fluid loss such as diarrhea and vomiting. The increased erythrocyte counts in these situations may therefore only reflect the change in the plasma compartment rather than alterations in the production or fate of red blood cells. A sudden release of erythrocytes due to splenic contraction is another cause of a relative erythrocytosis (Duncan *et al.*, 1994). In pre-clinical studies, a pharmacologically absolute erythrocytosis may be expected if either EPO activity or enhancement of EPO activity is present.

Increased platelets may be seen with blood loss, inflammation and iron deficiency. The cytotoxic drug 5-fluorouracil causes an immediate fall and then a sustained increase in platelet numbers. Other compounds causing thrombocytosis are the drugs AZT and vincristine and the food additive butylated hydroxytoluene. The mechanisms involved in drug-related thrombocytosis are unclear, although cytokines including stem cell factor and interleukin-6 have been implicated. Thrombocytosis is often synchronous with

reticulocytosis, supporting the hypothesis that EPO has a stimulatory effect on megakaryocytes (Boudreaux *et al.*, 1996).

#### *Thrombocytopenia/blood loss/coagulation inhibition*

Thrombocytopenia may be an artifactual finding due to platelet aggregation during or after sample collection, and this must first be ruled out as a cause before additional investigation is performed. Thrombocytopenia caused by drugs and chemicals may be directly caused by their cytotoxic effect on bone marrow progenitor cells, as noted with chemotherapeutic agents, by peripheral destruction due to immune-mediated mechanisms or by increased consumption due to a coagulopathy. Other than chemotherapeutic agents, chloramphenicol has been associated with thrombocytopenia in dogs and cats. Similarly, estrogen and interferons can cause destruction of stem cells resulting in marrow suppression and thrombocytopenia. Agents that can specifically destroy megakaryocytes include anagrelide, ethanol, estrogens, interferons and thiazide diuretics (Anthony *et al.*, 1994; Okamura *et al.*, 1994; Rodman *et al.*, 1997). Drugs associated with peripheral destruction of platelets include methyl dopa, levodopa and gold therapy. Toxins that induce thrombocytopenia include aflatoxin B1, brackenfern and trichloroethylene (Weiss, 2000). Xenobiotic-induced platelet destruction is due to either immune-mediated or nonimmunologic destruction (Bloom *et al.*, 1988; Shebuski, 1993). Hapten (neoantigen/compound epitope formation), induction of antibodies and immune complex formation are all possible mechanisms of immune-mediated platelet destruction.

The two main toxicologic consequences of platelet modulation are predisposition to hemorrhage and thrombosis. Nonsteroidal anti-inflammatory drugs have been known to cause blood loss anemia, which is thought to be due to gastrointestinal damage or ulceration secondary to the local inhibition of prostaglandin synthesis (George and Shattil, 1991). Aspirin decreases platelet function and aggregation and can also cause gastrointestinal ulceration resulting in hematemesis and melena in humans and animals.

Coumarin-like compounds, such as warfarin, inhibit the carboxylation of vitamin K-dependent coagulation factors II, VII, IX and X resulting in prolonged clotting times (Bloom, 1997; Bloom and Brandt, 1997). Cephalosporins are also responsible for prolonged clotting times by the same mechanism. Several antibiotics that cause eradication of gut microflora and thus lower the levels of available vitamin K can prolong coagulation and cause bleeding. Any toxic compound that results in liver failure (such as acetaminophen) will cause decreased synthesis of the coagulation factors needed for clotting and may result in bleeding.

#### *Toxic leukemogenesis*

A few examples of leukemogenic agents include aromatic hydrocarbons (benzene), alkylating chemotherapeutic agents and ionizing radiation. The development of leukemia is not highly predictable or dose related in humans (Irons, 1997). Exposure to chemical clastogens that cause chromosomal damage (benzene and its metabolites) results in genetic damage. In many cases the damage is reversible by DNA repair mechanisms. For example, the folic acid antagonist methotrexate causes transient *in vitro* DNA damage, but therapeutic use of the drug is not associated with the development of leukemia. However, a secondary insult may overcome natural DNA repair capability resulting in permanent chromosomal damage. Acute myeloid leukemia can be induced in rats by very small quantities of dimethylbenzanthracene or with ionizing radiation (Levine and Bloomfield, 1992; Andrews, 1998).

## CONCLUSIONS AND FUTURE DIRECTIONS

The hematopoietic system is very susceptible to a variety of toxic chemicals and drugs, and such toxic effects may result in financial liability in cases of preclinical drug development and mortality in clinical practice. Because of this, systematic examination of blood and bone marrow is a major requirement of clinical and preclinical toxicity studies, and it has become a routine part of diagnostic evaluation in the clinics when screening for toxic effects of drugs. In most cases, bone marrow toxicity can be assessed by evaluating complete blood cell counts, peripheral blood smears and bone marrow examination. Finding toxic effects of a test compound in a dose-related fashion and without adequate therapeutic margins can typically halt further development of the drug.

Compared to other areas of toxicology, the blood and bone marrow effects noted in preclinical species is often reliably translated to the clinics, since the pathologic mechanisms responsible for such effects are mostly similar across species (Reagan *et al.*, 2011). In addition, if an adverse finding is demonstrated preclinically but an adequate therapeutic index is present, a routine blood smear examination can easily be performed to monitor adverse findings in clinical patients.

In conclusion, it is possible for a toxicologist to systematically evaluate blood and bone marrow toxicity in laboratory settings and to devise a hypothesis for development of such toxicity. Because of this, it is imperative for toxicologists to understand the basic concepts of the hematopoietic system in order to interpret the results of toxicological studies.

# Immunotoxicity

Neerad C. Mishra and Mohan L. Sopori

## INTRODUCTION

The immune system has developed to counter hazardous molecules and biological factors that are foreign to the host. Unlike invertebrates, humans and vertebrate animals have the ability to develop an immune response that retains memory for the invading agent. Immune response may manifest as specific antibodies, proliferation of specific cytotoxic cells and clonal expansion of memory cells toward the invading agent. Generally, an immune response is protective and results in inactivation or destruction of the potentially harmful chemical or a pathogen. Because of its protective effects, the immune system provides strong survival advantage. Immunotoxicology is the science that evaluates the undesirable effects of chemicals and other toxic agents on the host immune system. Although intuitively the effects of water and air pollutants and food additives would be highly relevant to the health of domesticated and farm animals, veterinary immunotoxicology has not been pursued to any significant extent (Kende *et al.*, 1984). Therefore, the immunotoxic inferences described in this chapter are derived primarily from human epidemiology and animal models. Many of the health effects of chemicals, including those commonly used in the agricultural industry such as herbicides and pesticides, might be contributed by their immunotoxic effects. Pathogens such as tuberculosis and human immunodeficiency virus (HIV) promote their survival through their ability to compromise the immune system.

## Historical background

Although the modern discipline of immunotoxicology is relatively new and immunology itself is nearly a century

old, concern with infections and their possible prevention dates back nearly one thousand years. It was realized long ago that survivors of smallpox or plagues were relatively resistant to the disease they had acquired earlier, and people in China, for example, were inhaling dried smallpox scabs to prevent infection as early as the 11th century. It was not until the late 19th century that boosting immunity with vaccination for specific infections was possible. The cellular basis of immune responses was recognized in the middle of the 20th century. The same period also saw the realization that inadvertent exposure to chemicals and even the therapeutic use of drugs may influence the optimal mounting of immune responses against invading organisms. There were occasional published reports of immunotoxic effects by environmental chemicals, especially pesticides, prior to 1970; a systematic study of immunotoxicity of various chemicals followed that period.

The search for drugs that modulate immune functions predates the experimental approach in immunotoxicity and has also provided valuable information about immune mechanisms. It was also known some time ago that environmental factors are important for development of cancer or certain autoimmune diseases; this information has led to screening of various chemicals for their untoward effects on the immune system. Yet, the information regarding the immunotoxicity of chemicals is often incomplete, controversial and has little relevance to doses or concentrations which are encountered in normal environmental exposures.

## Immunotoxicity in animal health

The study of immunotoxicity in a veterinary setting is an important issue. Although the study of veterinary immunotoxicology has not been pursued extensively, its

relevance to animal health is obvious. Most of our information on veterinary immunotoxicity comes from the extension of results from rodent experimental models. Some of the relevant areas are discussed below.

### *Infectious diseases*

The immune response is critical to the survival of the host against infections. Following an infection, a vertebrate defends itself by relatively non-specific innate and specific adaptive immune responses. Even a mild infection in an immunosuppressed host may cause life-threatening illness or death. Children and young animals are not fully immunocompetent, and weaker immunity may suppress growth and productivity in livestock. For example, because of relative weak immunity, waterborne *Cryptosporidium* may cause cryptosporidiosis – an opportunistic infection in immunocompromised animals, leading to significant economic losses.

### *Interference with vaccination*

Many chemical contaminants in water and soil have been shown to be immunosuppressive in animal models. For example, in the U.S., livestock is routinely vaccinated against common epizootic infections and the health of the vaccinated animals has notably improved. However, the efficacy of these vaccines may be compromised by immunosuppressive chemicals in the environment. Therefore, understanding the immunotoxicity of chemical contaminants at environmentally relevant concentrations is very important to ascertain their effects on animal health and efficacy of vaccines.

### *Immunotoxicity and cancer*

Environmental chemicals have the potential to cause cancers. This has been shown to be the case in experimental animal models with chemicals such as polycyclic aromatic hydrocarbons. Both innate and adaptive immune responses play a role in cancer surveillance, but immunosuppression induced by environmental chemicals may induce and promote tumor growth. Athymic mice lacking functional T cells are more susceptible to transplanted tumors suggesting that T cells are important in limiting the growth of tumors. Moreover, activation of cancer-specific immunocompetent cells is a promising new method for cancer treatment (Quezada *et al.*, 2011). Thus, exposures to immunosuppressive chemicals may lead to increased incidence of tumors and higher morbidity and mortality in livestock.

### *Autoimmunity*

An immune response is an exquisitely well-balanced act with built-in positive and negative modifiers. While weaker immune responses may cause immunodeficiency

and increased susceptibility to diseases, excessive immune response may lead to autoimmune disorders. Many small molecules are not immunogenic *per se*, but may interact with other molecules such as tissue proteins, leading to an immune response to “modified self” antigens and development of autoimmunity and hypersensitivity reactions. This has been elegantly demonstrated with many different small molecules, including procainamide, iodine and dioxin (Pollard *et al.*, 2010). Similarly, some infections may promote immune responses to self antigens through cross-reactivity. Thus, human rheumatoid heart disease may develop from streptococcal infection (Guilherme and Kalil, 2010). A number of autoimmune disorders in humans and animals are controlled by genetic susceptibility, but environmental chemicals may be a trigger in genetically susceptible individuals. In humans, autoimmune disorders are generally treated with immunosuppressive drugs; however, this option may not be economically practical in livestock.

## IMMUNE SYSTEM

To understand immunotoxicology, it is important to summarize basic concepts of immunology. A detailed description of the immune system can be found in *The Immune Response, Basic and Clinical Principles* by Mak and Saunders (2006). Vertebrates are capable of two types of immune responses: innate and adaptive (acquired) immunities. Although both innate and adaptive immune responses distinguish between self and non-self antigens, the mechanisms involved in the recognition of self and non-self antigens are different between the two responses. Both types of immune responses must operate normally to achieve optimal defense against pathogens. Generally a foreign entity is recognized by one or more subtypes of immune cells at mucous membrane interfaces – potential entry sites for pathogens, leading to initiation of an immune response.

### Cellular components of the immune system

The immune system comprises a wide variety of cells that communicate with each other and other cell types to mount an effective immune response. Different types of immune cells and their surface markers are listed in Table 23.1. Cells mediating innate and adaptive immune responses are white blood cells or leukocytes. In mammals the primary source of leukocytes is bone marrow and the thymus, and there are several different subtypes of leukocytes. These cells are found throughout the body and are described on the following page.

TABLE 23.1 Cellular components of the immune system and their functions in mammals

Cell types	Specific cell surface markers	Functions
Stem/progenitor cells	CD34, CD90, CD110, CD111, CD117, CD133, CD202, CD243	Differentiate into hematopoietic cells, including erythrocytes and leukocytes
T lymphocytes	CD3, CD4, CD5, CD7, CD8, CD25, CD28, CD45R, CD52L, CD69, CD134, CD152, CD154	Generation of Th and cytotoxic T cell subsets, memory T cells and production of cytokines
T helper lymphocytes (Th1, Th2 and Th17)	CD2, CD3, CD4, CD28, CD45R, IL23R	Help maturation of T and B cells
Cytotoxic T lymphocytes (CTLs)	CD3, CD8, other lymphocytic markers, but not CD4 and IL-23R	Cause lysis of specific antigen-bearing target cells; graft rejection
NKT cells	CD11b, CD16a, CD56, CD69, CD94, CD152, CD158a, CD161	Lysis of viral-containing cells and tumor cells
B cells	Lymphocyte markers + CD21, CD35, CD40, CD45	Differentiation into antibody producing cells, antigen presentation to T cells
Plasma cells	CD38	Antibody production
Monocytes, macrophages	CD11b, CD13, CD14, CD64, CD80, CD86, CD115, MHC class II	Phagocytosis, inflammatory responses, cytokine production, antigen presentation to T cells
Dendritic cells	CD1a, CD11c, CD80, CD83, CD86, CD123, CD205, CD207, CD209	Antigen presentation to T cells
Mast cells	CD33, CD117, CD203c	Release of vasoactive products, anaphylaxis, wound healing, defense against pathogens
Granulocytes	CD15, CD16b, CD31, CD88, CD156a	Phagocytosis, inflammation

Phenotypes indicated refer to human cells; only human and mouse cells are extensively analyzed. Only differentiating markers are indicated. Information on most domestic animals is limited.

Source: eBioscience, San Diego, CA.

### Neutrophils

Neutrophils, also referred as polymorphonuclear neutrophils (PMNs), are granulocytes. They are the most abundant type of leukocytes in mammals and contain a nucleus divided into 2–5 lobes. While they are normally found in the blood, they are the first responders during acute inflammation as a result of infection or tissue injury. Chemotaxis allows them to migrate to the site of inflammation/injury where they release cytokines that amplify the inflammatory response. Neutrophils provide the front-line defense against invading pathogens by digesting them in phagosomes (Segal, 2005). Neutrophils act by ingestion (phagocytosis), release of anti-microbial granules and formation of “extracellular traps” composed of chromatin fibers and serine proteases (Brinkmann *et al.*, 2004). Low neutrophil count (neutropenia) makes the host highly susceptible to infection.

### Macrophages

Macrophages are differentiated monocytes in tissues. Like neutrophils, macrophages are phagocytes and can engulf pathogens and cell debris, removing necrotic cells from the site of inflammation, including neutrophil debris. In mice, macrophages express CD14, CD11b and F4/80. Macrophages are important in both innate and adaptive immunities. Trapped material such as pathogens is taken into phagolysosomes where enzymes and toxic peroxides digest the pathogens and other trapped cellular proteins.

In addition to innate immunity, macrophages have the ability to present processed antigens to T cells to initiate the adaptive immune response. They may also help in muscle regeneration by elaborating soluble substances that stimulate proliferation, differentiation, repair and regeneration of muscle. Macrophages have different names in different tissues: dust cells/alveolar macrophages in the lung, histiocytes in connective tissue, Kupffer cells in the liver, microglia in the nervous tissues, epithelioid cells in granulomas, osteoclasts in the bone and sinusoidal lining cells in the spleen. Some bacteria and viruses are resistant to lysosomal degradation in macrophages and these cells become sanctuaries for these pathogens, including *Mycobacterium tuberculosis* and human immunodeficiency virus (HIV).

### Dendritic cells

Dendritic cells have dendrites (branched projections) and act as highly potent antigen-presenting cells (Banchereau and Steinman, 1998). Dendritic cells are present in tissues that are in close contact with the environment, including the skin (Langerhans cells) and inner lining of the nose, the lung, the stomach and the intestines. Once activated the cells migrate to lymph nodes, where they interact with T cells and B cells to initiate the adaptive immune response (Sallusto and Lanzavecchia, 2002). Dendritic cells are of two types: myeloid and plasmacytoid. Myeloid dendritic cells evolve from myeloid

precursors, express Toll-like receptor 2 (TLR2) and TLR4, and produce IL-12 upon activation. Plasmacytoid dendritic cells are derived from lymphoid precursors, express TLR7 and TLR9, and secrete large amounts of type I interferon (interferon- $\alpha$ ).

### Natural killer (NK) cells

NK cells are large granular lymphocytes that possess the ability to kill targets without specific antigenic activation. These cells play a major role in the surveillance of spontaneous tumors and death of virus-infected cells. Several cytokines have been implicated in the activation of NK cells; these include IL-12, IL-15, IL-18, IL-2 and CCL5. NK cells also express CD16, that upon binding to the Fc portion of an antibody, kills the cells through antibody-dependent cellular cytotoxicity (ADCC). Cytoplasmic granules in NK cells contain perforin and granzyme that cause pore formation and lysis, respectively, in target cells (Oldham, 1983).

### B cells and T cells

These are two major lymphocyte subtypes that are involved in adaptive immunity. Both T and B cells are derived from bone marrow cells; however, while B cells mature in the bone marrow, T cell maturation occurs in the thymus. In the thymus, through positive and negative selections, T cells learn to distinguish between “self” and “non-self,” which is critical for the generation of tolerance to self antigens (Klein *et al.*, 2009). T cell and B cell receptors are clonally generated by random recombination of certain segments of DNA. T cell receptors (TCRs) and B cell receptors (BCRs) have enormous diversity and each naïve cell recognizes a unique antigenic determinant (epitope). B cells produce and secrete antibodies, while T cells differentiate into helper and cytotoxic T cell types. B cells can bind soluble antigens, but T cells recognize antigenic determinants only in association with self major histocompatibility (MHC) antigens on an antigen presenting cell. Depending on the type of TCR expressed, there are two major classes of T cells:  $\alpha/\beta$  TCR-containing cells (>90%) express the TCR that is a heterodimer of  $\alpha$  and  $\beta$ , while  $\gamma/\delta$  T cells (<10%) express TCR made from a heterodimer of  $\gamma$  and  $\delta$  TCR chains; compared to  $\alpha\beta$  TCR,  $\gamma\delta$  TCR exhibits limited diversity. Mature T cells with  $\alpha\beta$  TCR have two major subtypes:  $CD4^+$  and  $CD8^+$ .  $CD8^+$  T cells bind epitopes that are part of class I MHC antigens and  $CD4^+$  T cells recognize antigenic epitopes in association with class II MHC antigens. Both B and T cells have the ability to become memory cells that recognize specific antigens.

T-helper (Th) cells are  $CD4^+$  T cells which can be functionally divided into three subtypes: Th1 cells primarily produce interferon- $\gamma$  and proliferate in response to IL-12. They act as helper T cells for generation of cytotoxic T cells. Their function is regulated by STAT1 and STAT4,

and they contain the lineage-specific transcription regulator T-bet. Th2 cells are the major producers of IL-4, IL-5 and IL-13, and proliferate in response to IL-4. Th2 cells play a critical role in the defense against parasites and are also involved in allergic responses and asthma. The function of Th2 is regulated by STAT6 and contains the lineage-specific transcription factor GATA3. Th17 has been recently recognized as a new lineage of  $CD4^+$  T cells that express IL-23 receptor and produce IL-17 and IL-21. Th17 cells proliferate in response to IL-6 and IL-13, and contain the lineage-specific transcription factor ROR $_{\gamma t}$ . They are proinflammatory and play an important role in the host defense against infection by recruiting neutrophils and macrophages to infected tissues. Th17 cells are increasingly being recognized as key players in autoimmune and inflammatory diseases (Dong, 2008). Table 23.2 describes major cytokines and their functions.

### General features of innate immunity

The immune system is primarily built to defend against infections that result from attachment and entry of pathogens into the body. Apart from acquired immunity, the body has several defense mechanisms to thwart and limit infections. Skin is the largest organ in the body and forms a strong physiological barrier against the entry of pathogens into the body. Secretions such as mucus in the airways (mucociliary train) and gut, and acid and hydrolyzing enzymes in the stomach, help to clear the invading pathogens before they make contact with tissues.

The innate immune response does not make fine distinctions among invading entities and does not cause permanent changes in the immune system (i.e., the response to a second exposure by the same foreign entity does not differ in the kinetics or the magnitude from the response to first encounter).

Specialized phagocytic cells such as neutrophils and macrophages express cell surface receptors to recognize pathogens and their molecules. In recent years, TLRs have been intimately linked to innate immunity and shown to be critical in the recognition of microbial elements and their products. TLRs are a group of pattern recognition receptors (PRRs) that recognize microbe-associated molecular patterns (MAMPs) such as lipopolysaccharides, bacterial proteins, CpG DNA motif, double stranded RNA and flagellin. Table 23.3 shows specific ligands (MAMPs) of some important TLRs.

TLRs are type I transmembrane proteins composed of extracellular, transmembrane and cytoplasmic domains. The extracellular domain recognizes specific microbial elements and the intracellular domain mediates the intracellular signaling as a consequence of interaction between TLRs and MAMPs (Palm and Medzhitov, 2009). So far ten TLRs have been identified in human genome (TLR1-TLR10). TLR1, TLR2, TLR4, TLR5 and TLR6 are anchored

TABLE 23.2 Important cytokines and their major sources of production

Cytokine	Source(s)	Function
TNF $\alpha$	Macrophages, mast cells, NK cells	Regulation of cytokine expression and cell adhesion molecules; tumor cell death
TNF $\beta$	Th1 and cytotoxic T cells	Phagocytosis, cell death; NO production
IFN- $\gamma$	Macrophages, Th2 cells, NK cells, activated B cells	Elimination of pathogens; switching of Ig classes; inhibits viral replication and cell proliferation; homeostasis of respiratory epithelium
TGF $\beta$	Monocytes, T cells	Chemotaxis of macrophages; IL-1 activation; IgA synthesis; differentiation of Th17 cells
MIF	Macrophages, lymphocytes	Chemotaxis of monocytes and T cells
IL-1 $\alpha$ and IL-1 $\beta$	Monocytes, macrophages, dendritic cells; B cells	Activation of Th and NK cells; B cell amplification; inflammation
IL-1Ra	Macrophages, monocytes	Inhibits IL-1 and IL-2 action
IL-2	Th1 cells	Activation, proliferation, differentiation of T cells, B cells and NK cells
IL-3	Th cells, NK cells, monocytes	Growth and differentiation of stem cells and mast cells; degranulation of mast cells
IL-4	Th2 cells	T cell and B cell proliferation and differentiation; MHC II expression on macrophages
IL-5	Th2 cells	Proliferation and differentiation of activated B cells; IgA synthesis; eosinophil growth
IL-6	Macrophages, monocytes, Th2 cells, stromal cells	Maturation of B cells into plasma cells; antibody secretion; differentiation of stem cells; acute phase response; inflammation; inhibition of Tregs
IL-7	Bone marrow and thymus stromal cells	Differentiates stem cells into progenitor T and B cells
IL-8	Macrophages, endothelial cells	Neutrophil chemotaxis
IL-10	Tregs	B cell activation; inhibition of Th1 responses
IL-12 (p70 and p40)	B cells, monocytes, dendritic cells	Differentiation and activation of cytotoxic T cells and NK cells; induction of IFN
IL-13	Th2 cells	Th2 cell differentiation; mucus production in the lung; B cell proliferation; defense against nematodes
IL-15	Dendritic cells, macrophages, epithelial cells	NK cell development; $\gamma\delta$ T cell development; mast cell proliferation
IL-17	Th17 cells	Inflammatory response and defense against pathogens; autoimmune diseases
IL-21	Th17, NKT cells	Differentiation of Th17 cells; inhibition of Tregs; autoimmune diseases
IL-23	Macrophages, dendritic cells	Proliferation of Th17 cells; autoimmunity

TABLE 23.3 Ligands for some Toll-like receptors

TLRs	MAMPs
TLR2	Bacterial lipoproteins, lipoteichoic acid, peptidoglycan, Zymosan
TLR3	Double stranded RNA
TLR4	Lipopolysaccharide
TLR5	Flagellin
TLR & TLR8	Single stranded RNA
TLR9	Unmethylated CpG DNA

into plasma membrane, while TLR3, TLR7, TLR8 and TLR9 are endosomal. Interaction between TLRs and its ligands leads to activation of mitogen-activated protein kinases that leads to the activation of transcription factors such as the nuclear factor  $\kappa$ B (NF- $\kappa$ B), activator protein-1

(AP-1) and interferon-regulatory factors (IRFs); these factors are involved in immune and inflammatory responses against microbes. Impaired microbial recognition through genetic defects in PRRs may lead to serious diseases. For example, aberrant TLR5 activation has been linked to inflammatory bowel disease in human and rodents. TLRs also promote acquired immunity through induction of costimulatory molecules on antigen-presenting cells (Li *et al.*, 2009). Thus, TLRs are important both for innate and adaptive immune responses.

### General features of adaptive immunity

Adaptive immunity differs from innate immunity with respect to specificity, memory, diversity, tolerance and “division of labor” (Mak and Saunders, 2006).

### Specificity

Specificity indicates that the response is specific to a unique antigen either by the antibody produced by B cells or effector T cells expressing antigen-specific receptors. T and B cells expressing randomly generated TCR and BCR, respectively, are selected by and proliferate in response to specific antigenic epitopes. However, antigens with closely related epitopes to the inducing antigen may exhibit some degree of cross-reactivity with the effector cells or the antibodies to the antigen. Nonetheless, unlike the broad recognition of TLRs, the range of binding specificities of a lymphocyte is very limited.

### Immunological memory

An adaptive immune response is characterized by development of memory that facilitates the response to the repeat antigen both in time and magnitude. This immunological memory is the basis of vaccination and development of secondary immune response that protects the host from the same or similar pathogen. The mechanism of memory cell development is not fully understood; however, during the antigen-induced clonal expansion of lymphocytes, some daughter cells differentiate into long-lived memory cells that bear the antigenic receptors identical to the TCR involved in initial recognition of the immunizing epitope.

### Diversity

An innate immune response has a limited capacity to recognize an antigen. On the other hand, the capacity of the adaptive immune response is limitless with an estimated number of distinct randomly generated receptors that recognize antigens exceeding  $10^{12}$ . This incredible potential number of receptors suggests that mammals are capable of responding to any conceivable molecule. As discussed under immunological cells, this degree of diversity in BCRs and TCRs arises through somatic gene rearrangement during the development of B and T cells.

### Immunological tolerance

Because we have BCRs and TCRs that recognize virtually anything, there has to be a mechanism that limits our ability to react to our own (self) antigens. Tolerance to self antigens results from the screen in the thymus through the positive and negative selection processes that eliminate T lymphocytes with significant self reactivity. Similarly, maturing B cells undergo a central tolerance process in the bone marrow. In addition, there are peripheral tolerance mechanisms that operate outside the thymus and bone marrow and ensure that a normal host does not elicit significant immunological reactivity to self antigens. Discussion of the peripheral tolerance mechanisms is beyond the scope of this chapter and

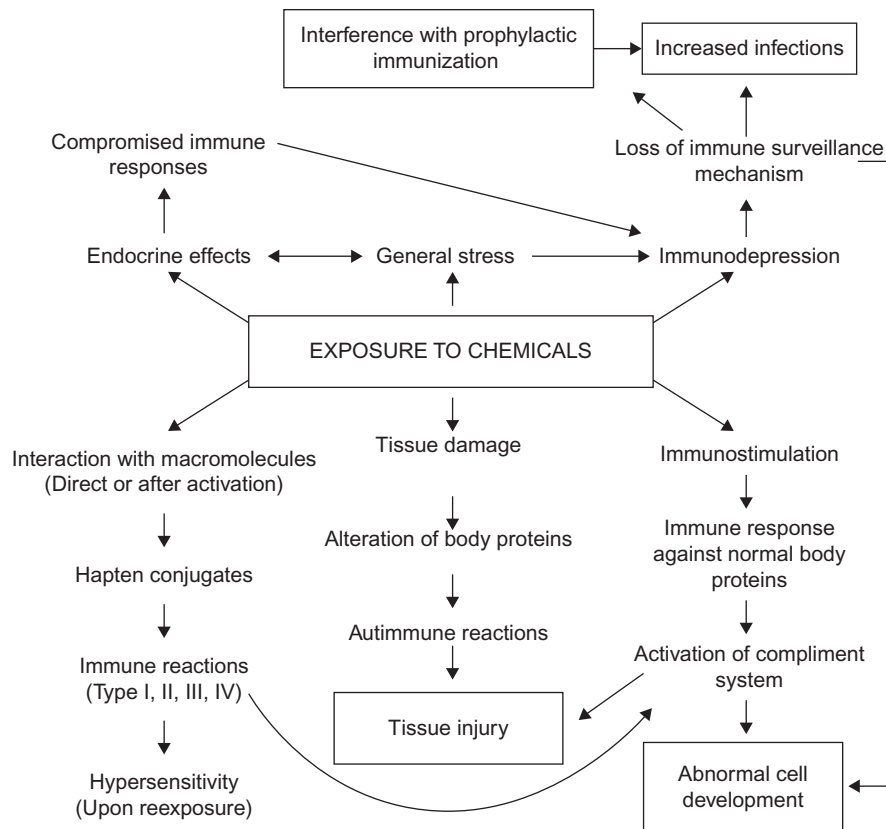

is reviewed in Yarkoni *et al.* (2010), Thomas (2010) and Mueller (2010). Breakdown of immunological tolerance may lead to autoimmune diseases.

### Division of labor

Pathogens come in different flavors; some are intracellular while the others are extracellular. Similarly, immune responses against cancer cells and transplanted tissues would be somewhat different from those against pathogens. The adaptive immune response has evolved to entrust different jobs to different effector cells. Thus, B cells recognize extracellular bacteria or bacterial products and mount the humoral (antibody) response. Binding to the antibody marks these molecules/cells for elimination by phagocytic cells such as macrophages. T cells are incapable of recognizing soluble antigens; therefore, the B cell is the primary cell type to defend against extracellular entities. On the other hand, antibodies are unable to penetrate cell membranes to attack intracellular pathogens. This is accomplished by the cell-mediated immune response that is mounted by T cells. T cells recognize foreign antigens on the cell surface of an infected cell and generate the antigen-specific cytotoxic T cells that kill the host cells carrying the foreign antigen. Both cytotoxic T cells and B cells require products of T helper cells for proliferation and differentiation. Helper T cells have the function to help the growth and differentiation of B cells and cytotoxic T cells. T cells such as regulatory T cells (Tregs) help in containing the innate and adaptive immune responses from going into overdrive and causing tissue damage.

### Relationship between innate and adaptive immune responses

The innate immune response is critical in limiting the access of pathogens until the development of specific lymphocytes of the adaptive immune response. Therefore, the innate immune response is the first line of defense against pathogens. It should be emphasized that in many instances the innate immune response successfully eliminates pathogens even before the adaptive immune response becomes functional. Moreover, the molecules essential for development of the adaptive immune response are produced by the cells of the innate immune system. In addition, the cells in the innate immune response synthesize chemokines (chemo-attractants) that guide the migration of the effector lymphocytes to the site of infection/injury. Similarly, the activated lymphocytes secrete products that activate large numbers of the innate immune response cells. Thus, the two responses are interdependent for optimal defense against pathogens.

**FIGURE 23.1** A hypothetical scheme depicting various pathways by which a chemical may produce immunotoxic effects, immune-mediated tissue injury and/or disease. Adapted from [Sharma \(1984\)](#).

### Possible mechanisms of immunotoxicity

Exposure of animals to toxicants may have effects on their immune system by a variety of mechanisms. Not only is the immune system profoundly influenced by other organs or systems of the body, but the complexity of immune responses also provides multiple targets for effects of chemicals. A generalized scheme of how chemicals may influence the immune system is illustrated in [Figure 23.1](#). Both immunosuppression and excessive immunostimulation are undesirable for the general health of animals. Chemicals may affect protein synthesis required for cell proliferation as well as antibodies. Chemicals that have potential for alkylating nucleic acids or proteins are immunotoxic because they interfere with the function of various proteins in the immune responses. Some mycotoxins or their metabolites are highly reactive in mammals and may bind to or destroy tissues. The acquired immunity depends largely on cellular proliferation and any substance that interferes with proliferation of immune cells will cause immunosuppression.

Chemicals may interfere with the function of enzymes directly, which is required in the immune processes.

Activated esterases may degranulate mast cells, releasing histamine, and may be involved in the process of chemotaxis by polymorphonuclear cells. Protease inhibitors will interrupt the post-translational processing of various cytokines and can interrupt their release. Chemicals likely to modify cell membrane functions will have a similar effect. By altering cytokine signaling, chemicals may profoundly alter differentiation of immune cells, such as lymphocyte subtypes, and since various cellular components have synergistic or antagonistic function, the homeostasis of the immune system is likely to be disrupted. Some chemicals, particularly biologically reactive immunogens, can selectively eliminate specific cells of this system. For example, chemicals that can destroy macrophages will interrupt antigen processing and presentation to other cells for mounting an effective immune response.

Immune responses may cause tissue damage or can be mediators for causing health problems in animals. Allergy or hypersensitivity is a good example where the well-being of the animal can be compromised. The allergic reactions require initial sensitization and later a challenge exposure to a chemical to mount the response.

Four distinct types of allergic mechanisms have been described (Gell and Coombs, 1975), all of which lead to inflammatory processes. Type I hypersensitivity is IgE mediated where specific IgE link on mast cells, a subsequent challenge to either the same or an antigenically similar chemical causes degranulation releasing bioactive substances. This type of reaction is exemplified by asthma, hay fever, food allergy or anaphylactic reactions. Type II allergy is also antibody mediated; in this case the antigen may be cell bound and reacts to specific IgG- or IgM-type antibodies. The cell may be destroyed by either complement activation or phagocytosis. Drug-induced hemolytic anemia is a good example of such a reaction. Type III hypersensitivity requires a complex formation of the antigen with IgG or IgM antibodies, the immune complex may trigger complement activation leading to inflammatory changes, such as in Arthus reaction (localized edema or infiltration resulting in abscess or gangrene). The type IV hypersensitivity is cell mediated, where sensitized T helper lymphocytes react with the antigen, resulting in activation of macrophages and release of inflammatory mediators.

## Cooperation and interactions between immune and other systems

### *Immune mechanisms subsequent to pathologic damage*

The purpose of the immune functions is to ward off undesirable organisms or materials from the body, its relationship with inflammatory processes and pathologic damage is implied. Many of the cellular components of the immune system are also primary components in inflammation. Therefore it is natural that various components of this system are activated after damage to other tissues or organs of the body. The immune system responds to altered proteins or to other biological molecules formed by binding with reactive intermediates, which may be produced in the body subsequent to metabolic activation of a number of exogenous chemicals or due to tissue damage.

### *Control of the immune system by nervous system*

The immune system interacts with other systems and is profoundly influenced by the central nervous system, both directly via innervations of lymphatic organs and indirectly via neuroendocrine mechanisms. The autonomic nervous system directly innervates thymus, spleen, lymph nodes, bone marrow and other lymphoid tissues. Pharmacological manipulation of post-ganglionic noradrenergic nerve fibers affects immune functions. Neurotransmitters such as acetylcholine affect the function of immune cells and many immune cells have the ability to synthesize acetylcholine. Moreover, most immune cell types, including T cells and macrophages, express nicotinic acetylcholine receptors; activation of

nicotinic acetylcholine receptors by nicotine/nicotine-containing substances (e.g., cigarette smoke) or acetylcholine suppress inflammatory and adaptive immune responses (Sopori, 2002). The cells of the immune system produce factors that influence the nervous system.

### *Endocrine mechanisms*

Hormones, such as somatotrophin (growth hormone) and thymosin (thymic maturation factor), stimulate the immune responses, whereas steroids, including sex hormones, generally suppress the immune responses. Role of stress on immune functions has been shown; it is presumed that exposure to exogenous chemicals may induce stress. Stress-like effects after stimulation of the hypothalamic-pituitary-adrenal axis lead to cortisol production; the latter is a well-known immunomodulatory agent.

### *The complement system*

A complex system that consists of a cascade of serum proteins, mostly of  $\beta$ -class globulins, is present in most vertebrates. The function of this system is to enhance the action of antibodies by causing cell membrane alterations, often cytolysis. The complement combines with the Fc receptors of an antibody molecule and is enzymatically activated to a cytotoxic membrane attack complex. Immunotoxic chemicals may modify the complement function and may alter the inflammatory processes.

## IMMUNOTOXIC AGENTS

The structural and functional integrity of the immune system are crucial in performing its protective role against pathogenic agents. Thus, any chemically induced perturbation of the host's immune system can compromise its protective capacity and may lead to adverse health consequences for its host. A chemical substance should be considered immunotoxic when the undesired events of the chemical are: (1) a direct and/or indirect action of the xenobiotic (and/or its biotransformation product) on the immune system and (2) an immunologically based host response to the compound and/or its metabolite(s), or host antigens are modified by the compound or its metabolite(s). There is limited information on the immunotoxic effect of various chemicals in animals of economic importance. Most of the available data relate to either laboratory animals or are obtained from epidemiological studies in people.

### *Mycotoxins*

Mycotoxins are secondary metabolites of fungi and, if consumed through food or feed, are potentially

hazardous to human and animal health. Mycotoxins present a large spectrum of toxic effects; nevertheless, impairment of the immune response is a common feature of these food contaminants (Oswald *et al.*, 2003; Meisssonier *et al.*, 2008). In recent years there has been increasing awareness of the hazards imposed on both human and animal health by mycotoxins present in food and feed. Five classes of mycotoxins are of major concern in animal husbandry, namely aflatoxins, fumonisins, ochratoxins, trichothecenes and zearalenone. Due to their diverse structure these fungal toxins are able to cause a variety of symptoms in animals. The chemical diversity of mycotoxins and the wide range of matrices in which they can be found pose great challenges to analytical chemists. Therefore, a need exists for a reliable, economical and easy-to-use assay for the measurement of the mycotoxin content, especially in the raw materials for food and feed production (Cozzini *et al.*, 2008). Mycotoxins such as aflatoxin B<sub>1</sub> and fusarium T-2 toxin inhibit protein synthesis and cell proliferation, and some may have selective effects on various subpopulations of lymphocytes (Girish *et al.*, 2010). Several mycotoxins are cytotoxic to lymphocytes *in vitro*, perhaps because of their effects on membranes or interference with macromolecular synthesis and function. Selected effects of immunotoxic mycotoxins that have been studied in domestic animals are listed in Table 23.4.

Aflatoxin B<sub>1</sub>, a mycotoxin produced by *Aspergillus flavus* or *A. parasiticus*, is a frequent contaminant of food and feed. Aflatoxin B<sub>1</sub> exhibits immunosuppressive properties; ingestion of contaminated feeds increases susceptibility to infection (Joens *et al.*, 1981; Venturini *et al.*, 1996). Aflatoxin B<sub>1</sub> mainly exerts its effects on cell-mediated immunity (Bondy and Pestka, 2000; Wada *et al.*, 2008). It decreases lymphoid cell populations, especially the circulating activated lymphocytes, suppresses lymphoblastogenesis and impairs both cutaneous delayed-type hypersensitivity (DTH) and graft versus host response. Aflatoxin B<sub>1</sub> also decreases NK-mediated cytotoxicity and several macrophage functions, such as phagocytic activity, intra-cellular killing or production of oxidative radicals (Ghosh *et al.*, 1991). Effects of aflatoxin B<sub>1</sub> are primarily on the cell-mediated immune functions; however, T cell-dependent humoral responses are also adversely affected. Although many data on the effect of aflatoxins on immune cell functions are available, few studies have investigated their effects on cytokine expression and the results are somewhat conflicting. While *in vitro* treatment of human monocytes with aflatoxin B<sub>1</sub> on LPS activation led to decreased expression and release of IL-1 $\alpha$ , IL-6 and TNF- $\alpha$  (Rossano *et al.*, 1999), swine alveolar macrophages did not respond similarly to LPS (Liu *et al.*, 2002). *Ex vivo* analysis of peritoneal macrophages from mice orally exposed to aflatoxin B<sub>1</sub> indicated an increased expression of IL-1 $\alpha$ , IL-6 and

TNF- $\alpha$  (Dugyala and Sharma, 1996). Macrophages engulf large amounts of aflatoxin-bound macromolecules, which might explain their selective sensitivities to the toxin. Blood lymphocytes from pigs fed aflatoxin B<sub>1</sub> contaminated diet, when stimulated *in vitro* with mitogens, exhibited decreased expression of proinflammatory cytokines (IL-1 $\beta$  and TNF- $\alpha$ ) and increased expression of the anti-inflammatory IL-10 (Marin *et al.*, 2002; Meisssonier *et al.*, 2008). These results suggest that aflatoxin B<sub>1</sub> may depress many aspects of humoral and cellular immunities.

Fumonisins are well-known mycotoxins produced by *Fusarium verticillioides*, *F. proliferatum* and other *Fusarium* species. Different types of fumonisins have been structurally identified. The "B" series include the most prevalent type, the fumonisin B<sub>1</sub> (FB<sub>1</sub>), and it is estimated that toxin contaminates 59% of corn and corn-based products (Haschek *et al.*, 2001). Recently, fumonisins B<sub>2</sub> and B<sub>4</sub> were shown to be produced by *Aspergillus niger* isolated from coffee and grapes. Fumonisin B<sub>2</sub> was detected in coffee beans, wine and beer, adding to the list of foodstuffs that fumonisins contaminate (Scott, 2011). Consumption of food or feed contaminated with fumonisin B<sub>1</sub> can lead to disease in humans and animals. Fumonisins can cause liver and kidney toxicity, carcinogenesis, pulmonary edema and immunosuppression (Missmer *et al.*, 2006; Marin *et al.*, 2010). Their mode of action is not completely understood but they are known to influence the sphingolipid metabolism through the inhibition of ceramide synthase (Desai *et al.*, 2002). As fumonisins enter the body following consumption of contaminated food/feed, the intestine will be the first organ exposed to these toxins and negative effects of these toxins on the gastro-intestinal tract have been reported (Bouhet and Oswald, 2007). There have been a number of investigations involving fumonisin B<sub>1</sub> and immune responses (Bondy and Pestka, 2000; Devriendt *et al.*, 2009); and the toxins may affect mucosal immunity to pathogens. Several studies demonstrated that fumonisin B<sub>1</sub> affects innate immunity, as well as humoral and cellular responses of the acquired immunity (Bhandari and Sharma, 2002; Bouhet and Oswald, 2005; Marin *et al.*, 2007, 2010; Missmer *et al.*, 2006; Theumer *et al.*, 2002). Exposure to fumonisin B<sub>1</sub> was reported to cause localized activation of the cytokine network, suggesting that the toxin-induced changes in innate immune responses may be important in its immunotoxicity (Bhandari and Sharma, 2002; Bouhet *et al.*, 2006).

Ochratoxin A (OTA) is an immunosuppressive mycotoxin, produced by toxigenic species of *Aspergillus* and *Penicillium* fungi. Contamination of food by this mycotoxin takes place primarily during pre-harvest periods, and may contaminate any type of food. In addition, its chemical stability at high temperatures and during industrial food processing makes OTA one of the most

TABLE 23.4 Selected examples of immunotoxic effects of mycotoxins in domestic or food animals

Mycotoxins	Species	Observed effects	Reference
Aflatoxin B <sub>1</sub>	Swine	Decreased lymphocyte proliferation, macrophage migration, DTH and titers to SRBC	Oswald <i>et al.</i> (2005); Taranu <i>et al.</i> (2010)
	Bovine	Decreased lymphocyte proliferation <i>in vitro</i>	Paul <i>et al.</i> (1977)
	Chicken	Inhibitory effects on the function of PMNs Decreased cell mediated immunity and titers	Wada <i>et al.</i> (2010) Verma <i>et al.</i> (2004)
Deoxynivalenol	Swine	Activation of immune response Increased susceptibility to <i>Salmonella</i>	Malovrh and Jacovac-Strajn (2010) Vandenbroucke <i>et al.</i> (2009)
Fumonisin B <sub>1</sub>	Chicken	Decreased spleen cell viability and mitogenic response	Keck and Bodine (2006)
Ochratoxin	Swine	Reduced lymphocyte levels and apoptotic phagocytes	Müller <i>et al.</i> (1999)
	Chicken	Decreased cell-mediated immunity and titers	Verma <i>et al.</i> (2004)
Patulin	Rabbit	Reduced lymphocyte proliferation and serum immunoglobulins	Escoula <i>et al.</i> (1988a, b)
T-2 toxin	Swine	Impair acquired immune response	Meissonnier <i>et al.</i> (2008)
	Bovine	Reduced peripheral blood mononuclear cells proliferation	Charoenpornsook <i>et al.</i> (1998)
Zearalenone	Chicken	Modulate immune response to coccidial infections	Girgis <i>et al.</i> (2010)
	Swine	Divergent effects on innate immunity and cell proliferation	Marin <i>et al.</i> (2010)

abundant food contaminating mycotoxins. Due in part to its long serum half-life in man, almost 100% of all human blood samples from some geographic regions are positive for OTA. The immunosuppressive activity of OTA is characterized by decreased size of secondary lymphoid organs, such as the thymus, the spleen and the lymph nodes. OTA suppresses the antibody responses, alters the number and functions of the immune cells and modulates cytokine production (Müller *et al.*, 1999). The immunotoxic activity of OTA probably results from apoptotic and necrotic cell death of the immune cells together with their slow replacement due to the inhibition of protein synthesis (Al-Anati and Petzinger, 2006).

Patulin is produced by several *Penicillium*, *Aspergillus* and *Byssachlamys* species. Inconsistent reports on patulin toxicity in various species have created an unclear picture of potential harmful effects of patulin on the immune system (Escoula *et al.*, 1988a, b). Earlier studies in mice showed that patulin increased the number of splenic T cells, lowered serum Ig levels, depressed the DTH response, increased neutrophil count and increased the resistance to *Candida albicans*. On the other hand, patulin administration in mice and rabbits resulted in reduced lymphocyte blastogenesis and suppressed chemiluminescence response of peripheral leukocytes (Escoula *et al.*, 1988a; Sharma, 1993).

Trichothecenes, particularly deoxynivalenol (DON), are the most commonly encountered *Fusarium* mycotoxins (Pestka and Smolinski, 2005). The mechanism, human exposure and toxicological relevance of DON have been recently reviewed by Pestka (2010). The immunomodulatory effects of trichothecenes have been found to vary between immunosuppression and immunostimulation, depending on the dose, duration and time of exposure (Bondy and Pestka, 2000).

Trichothecene stimulates the immune system at low doses, but suppresses at high doses, mainly due to leukocytosis (Pestka, 2003; Desjardins, 2006). Repetitive exposure to high doses of trichothecenes may result in the injury to actively dividing cells in the bone marrow, intestinal mucosa, spleen and thymus (Desjardins, 2006). The ability to inhibit protein synthesis has been described as a major effect of trichothecenes (Bondy and Pestka, 2000; Desjardins, 2006). Low-dose trichothecene exposure transcriptionally and post-transcriptionally up-regulates expression of cytokines, chemokines and inflammatory genes with concurrent immune stimulation, whereas high-dose exposure promotes leukocyte apoptosis with concomitant immune suppression. DON and other trichothecenes, via a mechanism known as the ribotoxic stress response, bind to ribosomes and rapidly activate mitogen-activated protein kinases (MAPKs). The latter are important transducers of downstream signaling events related to immune response and apoptosis (Pestka *et al.*, 2004). T-2 toxin causes acute and chronic toxicity, and induces apoptosis in immune cells and fetal tissues (Li *et al.*, 2011). T-2 and DON cause severe depletion of T cells and are immunosuppressive *in vivo* and *in vitro*. Although immunosuppressive in mice, paradoxically T-2 toxin increased the expression and production of IL-12, TNF- $\alpha$ , IFN- $\gamma$  and IL-2, but decreased IL-1 $\beta$  in a concentration-dependent manner in peritoneal macrophages and lymph nodes (Ahmadi and Riazipour, 2008). On the other hand, DON increased the production of both TNF- $\alpha$  and IL-1 $\beta$  by macrophages (Yang and Pestka, 2002; Döll *et al.*, 2009). Thus, the major immunopathological effects of trichothecenes might be related to their proinflammatory responses. Other mycotoxins found as food and feed contaminants may cause similar changes in the immune system.

TABLE 23.5 Selected metals evaluated in domestic or food animals for immunotoxic potential

Metals	Reported immunotoxic effects	Reference
Lead	Immunosuppression in cattle Decreased peripheral lymphocyte counts and depressed interferon $\gamma$ -like cytokine by splenocytes of chicken	Black <i>et al.</i> (1992) Lee <i>et al.</i> (2001)
Mercury	Suppressed immunocompetence in fish	Sweet and Zelikoff (2001)
Molybdenum	Decreased antibodies to swine erythrocytes in calves	Gengelbach and Spears (1998)
Copper	Higher titers to ovalbumin in heifers	Salzer <i>et al.</i> (2004)
Zinc	Reduced phagocytic activity of hemocytes Decreased antibody response but increased phagocytosis by peritoneal exudates cells in pigs Higher antibody titers to ovalbumin in heifers	Mottin <i>et al.</i> (2010) Van Heugten <i>et al.</i> (2003) Salzer <i>et al.</i> (2004)
Chromium	Increased antibody response to ovalbumin in calves Decreased lymphocyte proliferation and phagocytosis in carps	Chang <i>et al.</i> (1996) Steinhagen <i>et al.</i> (2004)
Selenium	Enhanced cell-mediated immune response in eiders	Wayland <i>et al.</i> (2002)
Vanadium	Increased IL-6 activity in macrophage supernatants	Qureshi <i>et al.</i> (1999)
Cadmium	Immunostimulation, induction of autoantibodies	Ohsawa (2009)

## Metals

The industrial activities from the last century have resulted in massive increases in our exposure to toxic metals such as lead, cadmium, mercury and arsenic; these are now present in the entire food chain. A few selected studies with metals involving domestic animals are listed in Table 23.5. Lead has been shown to impair immune function and/or host resistance to disease dating back to the 1960s. However, it is only in recent years that lead has been recognized as a new category of immunotoxicants that dramatically shift immune function without significantly affecting the number or sub-type distribution of immune cells in lymphoid organs (Dietert and Piepenbrink, 2006). Lead is of particular concern in veterinary practice as exposure and poisoning of domestic animals with this metal has been reported (Black *et al.*, 1992). Lead, mercury and nickel are immunosuppressive; however, low doses of selenium, zinc and vanadium are immunostimulatory (Qureshi *et al.*, 1999; Wayland *et al.*, 2002; van Heugten *et al.*, 2003). Mercury is ubiquitously present in the environment resulting in permanent low-level exposure in human populations. Mercury can be encountered in three main chemical forms: elemental, inorganic and organic, which can affect the immune system in different ways. Subtoxic doses of mercury induce highly specific autoantibodies and a generalized activation of the immune system (Vas and Monestier, 2008; Sheir *et al.*, 2010). Some reports show that lead and cadmium stimulate the production of cytokines and IgE antibodies that may explain the increased number of atopic diseases in populations exposed to these two metals (Skoczynska *et al.*, 2002).

Immunotoxic effects of heavy metals have been recently reviewed and mechanisms may be diverse

(Ohsawa, 2009). Metals may chelate biological macromolecules and may affect protein synthesis, membrane integrity and/or nucleic acid replication. While *in vitro* studies may unravel potential molecular mechanisms, they have little value in predicting the *in vivo* immunotoxicity and are often opposite to the immunological effects seen *in vivo*. In general, heavy metals may affect the number of circulating B cells, T lymphocytes, NK cells, memory cells and inflammatory responses.

## Pesticides

Organophosphorus (OP) pesticides are used extensively to control agricultural and household pests. These pesticides constitute a diverse group of chemical structures exhibiting a wide range of physicochemical properties. The primary toxicological action of OP arises from its inhibition of the enzyme acetylcholinesterase that degrades the neurotransmitter acetylcholine. The main toxicity of OP pesticides is neurotoxicity (Pope, 1999; Bajgar, 2004), but there is little consensus that OP pesticides are immunotoxic (Sharma, 2006). It has been reported that OPs affect the function of neutrophils (Hermanowicz and Kossman, 1984) and macrophages (Crittenden *et al.*, 1998), and suppresses antibody production (Johnson *et al.*, 2002) in animals and humans. There are very few papers that deal with the mechanism of OP-induced immunotoxicity (Galloway and Handy, 2003; Langley *et al.*, 2004; Li, 2007). Rabbits fed low doses of methylparathion were reported to have atrophy of the thymus cortex and fewer antibody-forming cells in lymph nodes; splenic morphology was also considerably altered. Diets containing cabaryl or carbofuran fed to rabbits reduced the numbers of activated lymphocytes in

lymph nodes, decreased the number of splenic germinal centers and produced atrophy of the thymic cortex. The immunosuppressive effect of carbaryl containing feed is also reported in chicken which includes reduced macrophage function and lymphocyte proliferation (Singh *et al.*, 2007).

Although malathione exposure did not affect the innate immune response, it suppressed humoral immune responses in birds (Nain *et al.*, 2011). Humoral immune response against *Salmonella typhimurium* infection was also decreased in rabbits exposed to malathion or dichlorvos. A single dose of malathion, parathion or dichlorvos at the concentration that causes cholinergic distress reduced the primary IgM response to sheep red blood cells (Johnson *et al.*, 2002).

The functional status of the immune system in female mice exposed to a single oral dose of dimethoate (16mg/kg) was evaluated by assessing cell-mediated and humoral immune responses (Aly and el-Gendy, 2000). Dimethoate decreased the spleen weight without affecting the body weight, decreased the number of erythrocyte rosette forming cells and the proliferative response of the spleen to T and B cell mitogens, i.e., phytohemagglutinin and lipopolysaccharide, respectively. Organophosphates triphenylphosphate and triphenylphosphine oxide primarily affected various parameters of innate immunity.

Various chlorinated hydrocarbon insecticides, such as dieldrin, dichlorodiphenyl-trichloroethane (DDT) and lindane, have been tested for immunotoxic effects. In animal models, DDT was shown to be immunosuppressive and decreased the host immunity against a wide range of invading pathogens (Banerjee *et al.*, 1997;

Kim *et al.*, 2004). Occupational exposures to DDT were also associated with immunotoxicity.

## Industrial and environmental chemicals

Animals are constantly exposed to a wide variety of foreign chemicals, many of which are potentially toxic and some cause clinical poisonings. Immunotoxic effects of common environmental chemicals are summarized in Table 23.6. Increasing use of chemicals such as brominated and chlorinated flame retardants have caused environmental contamination globally and may have adverse health effects in animals and humans. In 1973, polybrominated biphenyl (PBB) accidentally entered the food chain in Michigan, when Firemaster FF-1, a commercial flame retardant, was inadvertently added to cattle feed. Following the Michigan accident, a large number of animal studies showed that PBB causes immunotoxic effects in cattle and laboratory animals, including atrophy of various lymphoid organs and depressed antibody responses. On the other hand, cattle inadvertently exposed to PBBs (accumulating up to 30ppm PBB in body fat) showed no adverse immunological effects (Kateley *et al.*, 1982); however, spleens of the mink exposed to 10ppm of DE-71 exhibited increased germinal center and B cell hyperplasia (Martin *et al.*, 2007). Chlorinated phenols, found in a variety of foods, were also evaluated for immunotoxicity (Forsell *et al.*, 1981). PCBs are members of the halogenated aromatic hydrocarbon class of chemicals that include the prototype 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), the most toxic synthetic chemical known to date. TCDD and

TABLE 23.6 Selected examples of contaminants in feed that may influence immune responses in animals

Chemicals	Species and effects	Reference
Organochlorine insecticides	Accelerates the development of systemic lupus erythematosus in ovariectomized mice	Wang <i>et al.</i> (2007)
Organochlorine insecticide mixture	Elevated lymphocyte proliferation and leukocyte phagocytic activity after exposure in swine	Bilrha <i>et al.</i> (2004)
Polyaromatic hydrocarbon mixture	Enhances components of innate immunity in resident mummichogs, while actively suppressing humoral immune responses	Frederick <i>et al.</i> (2007)
Polychlorinated biphenyls	Decreased antibody titers and lower concentrations of IgG, IgM in blood, negatively affect the immune system of the glaucous gull chick	Sagerup <i>et al.</i> (2009)
Polychlorinated biphenyls	Decreased antibody titers, decreased thymus and bursa cellularity, suppressed antibody responses in juvenile chickens following an <i>in ovo</i> exposure	Lavoie and Grasman (2007)
Polychlorinated biphenyls and other contaminants	Decreased NK cell activity, T cell mitogen response, antigen-specific proliferation, mixed lymphocyte response and delayed-type hypersensitivity in harbor seals	Van Loveren <i>et al.</i> (2000)
Tributyltin and polychlorinated biphenyls	Suppressed antibody response and phagocyte oxidative burst activity in catfish	Regala <i>et al.</i> (2001)

other dioxin-like compounds suppress humoral immunity, mainly by interfering with B cell differentiation and antibody production (Dooley and Holsapple, 1988; Tucker *et al.*, 1986; Sulentic and Kaminski, 2011). Dioxin-like compounds also disrupt the development and maintenance of the acquired immunity (Zhang *et al.*, 2010). Atlantic bottled-nose dolphin and Baltic harbor seal populations have been found to be highly susceptible to immunosuppression by PCBs.

A number of other chemicals, particularly those used in the plastics industry, such as bisphenol A, may impair the immune response (Richter *et al.*, 2007). Inhalation of toluene diisocyanate vapor induces allergic rhinitis in mice (Johnson *et al.*, 2007). Immunotoxic effects of 20 different industrial chemicals, such as vinyl chloride, benzene and styrene, are reviewed by Veraldi *et al.* (2006).

Other chemicals and drugs

Many drugs have the capability to alter the function of the immune system and, therefore, are used therapeutically. On the other hand, several drugs may have immunotoxic side effects. Diethylstilbestrol (DES), dexamethasone (DEX) and cyclophosphamide are immunosuppressive chemicals and induce similar thymic pathophysiology; however, the mechanism of immunotoxicity of these compounds is not overlapping (Patterson and Germolec, 2006). DES is a synthetic estrogen and commonly used as a growth promoter in animals, suppresses both cell mediated and humoral immunity, and is a potent macrophage activator. Moreover, prenatal exposure to DES may alter the development and function of the immune system. Recent reports provide little support for the association between prenatal DES exposure and development of autoimmune diseases

(Strohsnitter *et al.*, 2010). Cyclophosphamide, a potent immunosuppressive agent and protein synthesis inhibitor, impairs both humoral and cell-mediated immune responses. In mammals, cyclophosphamide suppresses graft versus host reaction, depletes leukocyte subpopulations, and inhibits T and B cell mitogenesis.

TESTING FOR IMMUNOTOXICITY

The realization that environmental chemicals might adversely affect the immune system has raised serious public concern. There is no single or simple test that can be used to evaluate the immunotoxic effects of a chemical. We have listed some commonly employed immunotoxicity tests in Table 23.7. Because of the complexity of the immune system, the initial strategy to evaluate immunotoxicity of an agent is to apply a tiered panel of assays. The first tier is a general screen for immunotoxicity and, depending on the testing agency, may or may not include functional tests such as the measurement of antibody responses after *in vivo* antigenic challenge, NK cell activity or non-specific immune parameters (e.g., lymphoid organ histology, serum immunoglobulin levels). The second tier usually consists of tests that identify specific target cells and examines resistance to infectious agents or neoplastic potential. Several studies have shown that assessment of only a minimal number of appropriate tests may be needed to predict immunotoxicity successfully in rodents. In particular, assessment of humoral immunity, via quantitation of antigen-specific T-dependent antibody responses, has been shown to be the best single indicator of potential immunotoxicity of

TABLE 23.7 Clinical or toxicological tests indicative of compromised immunologic responses

Tests	Basic principle
Hematology and lymphatic organ weight and pathology	Immunotoxic potential may be derived on general toxicity studies by total and differential leukocyte counts, and when spleen, thymus and lymph nodes are examined.
Lymphocyte proliferation	Responses to T and B cell mitogens, either on cells derived from exposed animals or cells treated <i>in vitro</i> .
Lymphocyte phenotyping	Phenotyping of lymphocytes bearing different cell surface markers can be used in routine studies.
Antibody production	Antibody titers to commonly used vaccinations are useful. In laboratory animals antibodies against T cell-dependent or -independent responses can be employed. Both antibody titers and plaque-forming cells assay have been used.
Delayed-type hypersensitivity responses	These T cell-dependent responses are commonly employed in various smaller species; however, they can also be used in large animals.
Phagocytosis and cell migration	Leukocytes and macrophages can be evaluated for phagocytic activity and chemotaxis; production of various signaling molecules can be measured.
Cytokine/chemokine levels	Measuring levels of various cytokines/chemokines in serum, BAL fluid and/or in tissues is useful after toxicant exposure.
Resistance to pathogens	Bacterial, viral or parasitic infections that have known effects on immune parameters can be used. Mortality to sublethal infections can be of use in early stages.

a compound (Luster *et al.*, 1988). A potentially highly useful parameter to predict immunotoxicity may be cytokine production. Cytokines regulate a variety of immunological responses, including inflammation, apoptosis, hematopoiesis and adaptive immunity (Corsini and House, 2010). There is a growing belief that *in vitro* models of immune response would eventually eliminate the use of animals in biosafety testing (Corsini and Roggen, 2009). Relevant *in vitro* models for hypersensitivity, immunosuppression, immune activation and autoimmunity will be needed to bypass animal use for immunotoxicity testing. A great challenge will be to simulate multiple organ interaction in eliciting an immune response to a chemical in non-animal models. Current *in vitro* immunotoxic tests, in most instances, do not replicate *in vivo* results.

## CONCLUSIONS AND FUTURE DIRECTIONS

A major issue facing toxicological science today is how to evaluate the toxicological data from *in vitro* and animal models and define the safety levels for human exposure. The immunosuppressive potential of a chemical is of little use if the effects on the immune system occur at doses that are significantly higher than the toxic doses for other systems. Understanding the mechanism(s) of action and the structure–activity relationships might help in defining the immunotoxic potential of a chemical. Effects on profiles offer a strong promise to define the potential immunotoxicity of a chemical. Recent expansion in the knowledge of cytokine biology and the realization that cytokines play an important role in diseases have created a need for precise measurements of cytokines in various body fluids, tissues and cells. Cytokine analysis and quality control issues need to be resolved for the routine use of this parameter in evaluating immunotoxicity (Corsini and House, 2010).

# Toxicity of nanomaterials

*Deon van der Merwe and John A. Pickrell*

## INTRODUCTION

The toxicology of nanomaterials has emerged as a challenging field of investigation because the widely applied toxicological paradigm “the dose makes the poison” appears to break down when the toxicological effects of materials are investigated at the nanometer scale. At this scale, the physical–chemical characteristics of materials are highly dependent on unit size and shape, and their interactions with biological systems may differ markedly from chemicals in solution, and from larger particles. The mass of nanomaterial to which susceptible tissues are exposed therefore becomes relatively less important as a determinant of the degree of biological impact compared to the size and form of the material. Particles, fibers, rods or tubes with one or more dimensions <100 nm are generally referred to as nanomaterials, or more specifically as nanoparticles (also known as ultrafine particles), nanofibers, nanorods or nanotubes. Nanomaterials are formed in nature during combustion, geological processes and biological processes. They are also commonly produced unintentionally by man in processes such as power generation from coal, the combustion of fuels in automobiles and many other industrial, engineering and domestic activities. Additionally, and at a rate that is rapidly accelerating, nanomaterials are manufactured intentionally, through molecular-level engineering, to obtain materials with unique mechanical, optical, electrical, magnetic and chemical properties (Tsuji *et al.*, 2006; Richards, 2009). These materials can be referred to as engineered nanomaterials (ENMs). They form the core of a rapidly growing industry where ENMs are incorporated into a wide variety of manufactured products. The

increasing use of ENMs, and the uncertainties associated with their unusual and often poorly understood biological effects, creates concern regarding their potential for causing unanticipated adverse health effects.

Investigators continue to discover unique properties of materials at the nanometer scale (Hoet *et al.*, 2004). Commercialization of products that exploit these unique properties is increasing, and have already found commercial application in sporting goods, tires, sunscreens, sanitary ware coatings, stain resistant textiles and clothing, food products and electronics (Hoet *et al.*, 2004; Nel *et al.*, 2006; Tsuji *et al.*, 2006). The list of products incorporating nanotechnology is expected to continue to expand indefinitely. By some estimates, growth of nanotechnologies and use of ENMs will far exceed the impact of the industrial revolution; they are predicted to become a \$1 trillion market by 2015 (Nel *et al.*, 2006). However, in spite of the seemingly unstoppable success of this technology, the unique properties of ENMs also present considerable new challenges to understanding, predicting and managing potentially adverse health effects following exposure. Technological development and applications are outpacing research for safe use and documentation of health and environmental risk (Hoet *et al.*, 2004; Tsuji *et al.*, 2006). Although exposure to ENMs is often intentional and controlled, widespread use of increasing quantities of ENMs increases the likelihood of uncontrolled human and animal exposure to nanomaterials in quantities that may result in biological effects. The future success of nanotechnology will be influenced by the level of public acceptance of the risks from exposure to ENMs, relative to the benefits. The increased demands for development to obtain the promised benefits from nanomaterials are balanced by an increasing

need for a proactive approach in estimating the environmental and health costs (Ngo *et al.*, 2008).

Concerns regarding the suitability of traditional toxicological assessment methods for evaluating ENMs gave birth to a relatively new discipline, named nanotoxicology. The discipline can be defined as: “the study of the adverse effects of ENMs on living organisms and ecosystems, including the prevention and amelioration of such adverse effects” (Oberdörster, 2010). As with conventional chemicals, risk assessment will be the basis of assessing and regulating exposure to nanomaterials to protect human, animal and environmental health. Many applications will likely have limited, or at least manageable, exposures and effects, and are therefore expected to cause insignificant adverse health effects; however, these assumptions may be difficult to substantiate based on traditional assessment methods because the effects of ENMs may be unique, product specific and unpredictable from data derived from larger particles or from chemicals in solution (Hoet *et al.*, 2004; Tsuji *et al.*, 2006). Studies have shown that some ENMs are not inherently benign, and that they may distribute throughout the body, inducing inflammation, oxidative stress and other adverse effects (Nel *et al.*, 2006). The results of studies demonstrating ENM adverse effects should, however, be interpreted with caution, especially when very high experimental doses are used that may not represent realistic exposure scenarios. Meaningful risk assessments should address questions related to the identification of hazards, exposure assessment and toxicokinetics including persistence in cells and subcellular structures (Oberdörster, 2010). Assuming public acceptance, toxicologists’ experience with past “miracle” materials advises us that caution in using novel substances without fully evaluating potential health risks may be ill advised. The discovery of serious adverse health effects, such as asbestos-like effects associated with multiwalled carbon nanotubes, has prompted nanotoxicologists to recommend heightened caution in the release of ENMs until more adequate information becomes available. Moving forward, the field of nanotoxicology is faced with many challenges, including the need to modify our understanding of the concept of “dose,” which, at the nanoscale level, is dependent on multiple physical–chemical factors other than the familiar mass or concentration used in traditional toxicology. Another significant challenge is the dynamic nature of the physicochemical characteristics of materials at the nanoscale, which often change over time, and as a consequence of interaction with biological systems (Maynard *et al.*, 2011). The specific changes that occur and their implications for biological interaction depend on the specific nanomaterial. Metal oxide nanoparticles, for example, may aggregate and agglomerate without significant reduction of the total surface area of the agglomerate, but it may limit interaction with internal surfaces of the agglomerate

to substances that are small enough to penetrate the agglomerate (Pickrell *et al.*, 2010). Thus, unique effects, associated with repeated and combined exposures, are expected to emerge.

## NANOMATERIALS CHARACTERIZATION

The unusual physicochemical properties of ENMs are attributable to their morphology, composition and surface characteristics. In an effort to standardize the description of nanomaterials in a way that will reduce uncertainty in data interpretation and facilitate cross-comparison between studies, the Minimum Information on Nanoparticle Characterization (MINChar) initiative (MINChar Initiative, 2008) identified a list of parameters that should ideally be characterized during studies. The parameters include particle size and size distribution, agglomeration state and aggregation, particle shape, chemical composition, crystal structure, surface composition, purity and levels of impurities, surface area, surface chemistry (including reactivity and hydrophobicity) and surface charge. It was also recognized that the characteristics of ENMs may not be stable during storage, handling, preparation and delivery into biological systems. Since the media used for delivery may change ENM properties, particular emphasis should be placed on characterization of ENMs “as administered.” It was also recommended that responses should be interpreted against a range of dose metrics, including mass, surface area and number concentration.

Particles or particle agglomerates are usually not perfect spheres and are almost never singly dispersed. However, particle size is most often defined as the diameter of a sphere that is equivalent in the selected property to the particle measured; this makes it possible to conveniently plot size distributions of irregularly shaped particles or particle-agglomerates using a single value (diameter) along a single axis. The property most often described is volume or mass; that is, the diameter of a sphere of equal volume to the particle(s) in question (volume or mass diameter). In Figure 24.1, particle diameter is expressed as that which was the median (120 nm), surface area (250 nm) or volume (20  $\mu\text{m}$  (20,000 nm)). Peak distributions in this figure contain some agglomerates of smaller particles.

The changes in ENM surface characteristics following delivery into a biological system are of particular importance when biological interactions are assessed. Proteins attach selectively to nanoparticle surfaces to form nanoparticle-protein coronas. This process, which depends on the adsorption properties of nanomaterial surfaces (Xia *et al.*, 2010), can dramatically change particle surface

**FIGURE 24.1** Laser diffraction size data for “nanoscale” aluminum powder used for *in vitro* toxicity experiments. Note the apparent difference in size when depicted as a number distribution versus an area or volume distribution. This occurs because volume scales as the cube of the particle diameter and calculated area scales as the square. Each curve, if presented alone, would give an incomplete picture of the particle size distribution/state of agglomeration of the sample. The three curves will overlay only for an ideal spherical, monodisperse, unagglomerated system. By comparing changes in particle size distribution to that of an “ideal” dispersion, a qualitative assessment of the degree of agglomeration can be made. (Reproduced with permission of Powers *et al.*, 2006.)

characteristics and, consequently, interactions with biological systems. Combination with biological macromolecules may both detoxify nanomaterials, and promote uptake into cells that can reduce clearance and lead to chronic, degenerative changes.

Solubility can be an important determinant of biological response. Solubility is a function of chemical activity, specific surface area, radius and curvature, agglomeration and specific chemicals that are adsorbed to the ENM (Borm *et al.*, 2006). Larger, more densely aggregated particles will dissolve more slowly. Adsorbed organic chemicals will slow solvation (Powers *et al.*, 2006). Solubility of ENMs is inversely correlated with their biopersistence. Since solubility and chemical reactivity are strongly dependent on the physical-chemical environment; they should be measured in an environment as near to that of the target biological environment as possible. This can sometimes be accomplished with *in vitro* conditions closely simulating biological solutions. Specific interactions may be present in biological fluids that are absent in simple solvents. For example, when determining solubility and reactivity in the lung, it is important to consider not just solubility in water, but in fluids that bear significant resemblance to that of the epithelial lining fluid (ELF). A minimal ELF volume is predicted to be about 40 to 100 ml for mature humans. The pH varies from 6.9 at the end of inspiration, to 7.5 at the end

of expiration. Bicarbonate acts as a buffer, and the change in pH is caused by removing CO<sub>2</sub> of expiration (Langmuir, 1965). Bicarbonate concentration in lung simulant fluid increases the solubility of MgO (Pickrell *et al.*, 2009). Surprisingly, macrocrystalline (bulk) MgO is dissolved as extensively as nanosized MgO in lung simulant fluids in about 10–20 minutes. This paradoxical result suggests that bicarbonate chemical activity may have a direct relation to the rapid dissolution of MgO in lung simulant fluid related to its modest solubility in distilled water. Stoichiometry of the likely chemical species suggests a conversion of MgO to Mg(OH)<sub>2</sub> in aqueous media and a subsequent conversion to the hydrated carbonate. These phenomena serve to illustrate the potential error associated with studies conducted in simple solutions when attempting to predict activity in complex biological systems.

## ANIMAL OR TISSUE EXPOSURES

### *In vitro* exposures to nanomaterials

Early indicators for ENM-derived adverse health effects were needed for an adequate assessment cytotoxicity of different types of well-characterized ENMs; cytotoxicity

was used to infer relative risk (Brunner *et al.*, 2006). For this purpose, the authors chose a mesothelioma and a fibroblast cell line. Two assays were performed. The first was mean culture activity, indicated by mitochondrial activity in converting a formazan type of dye from its leukoform to an active dye. In addition, DNA content, indicating cell number, was measured. Other than the positive asbestos control, none had >20% of the particles larger than 200 nm. Specific surface area was also higher than the asbestos positive control (90–190 m<sup>2</sup>/g versus the 8.5 m<sup>2</sup>/g of the asbestos). Mass median sizes were 20 to 50 nm and surface area median sizes were 6 to 21 nm, although they differed in terms of the shape and degree of agglomeration (Brunner *et al.*, 2006). Soluble amorphous silicate, compared with a negative control, caused minimal response in either cell line, consistent with its anticipated lack of toxicity. Crocidolite asbestos had a significant reduction in both cell activity and cell number (DNA) in both cell lines. The mesothelioma cell line was more severely affected, perhaps reflecting its metabolic activity. This toxicity was consistent with expectations from a positive control. Calcium phosphate had no significant cytotoxicity at 3 days; these data are consistent with it having no toxicity like the negative control particle – amorphous silica. Insoluble metal oxides (TiO<sub>2</sub>, ZrO<sub>2</sub> and CeO<sub>2</sub>) had modest toxicity at 3 days of exposure, which was most prominent in mesothelioma cells. By 6 days of exposure, these cells had returned to normal. Morphologically, the high dose of zirconium oxide caused the appearance of decreased cell number and function, even after 6 days of incubation. These data are consistent with only a modest health effect relative to the positive control. Zinc and ferric oxide were slightly soluble and quite toxic to both cell lines after 3 days of incubation. The authors advance no specific explanation for zinc toxicity beyond chemical toxicity, but experimental conditions suggest considerable local particle concentrations. For iron, the toxicity resulted from free radical production from the Haber-Weiss reaction. Because this reaction occurred at 40-fold less than the chemical toxicity of iron, it is said to be specific for the nanoparticle.

*In vitro* analysis of particle size-related effects on alveolar macrophages, epithelial cells and neutrophils demonstrates size- and oxidant-dependent responses. Increased interleukin (IL)-6 in cultured lung cells suggested a pro-inflammatory, oxidant response. Reduced cell numbers, especially with Mn-containing nanoparticles, suggested cytotoxicity at high doses, probably from local concentration of particles (Pickrell *et al.*, 2010). These effects were observed after *in vitro* exposure to concentrated PM (2.5) ambient particles collected in real time. Oxidative stress, mediated by ROS, is an important mechanism of particle-induced lung inflammation (Tao *et al.*, 2003).

## Intratracheal instillation and pharyngeal aspiration

### Ultrafine particles

Exposure to ambient air pollution particles caused increased cardiopulmonary morbidity and mortality, particularly with pre-existing disease (Tao *et al.*, 2003). Exacerbation of pulmonary inflammation in susceptible people (e.g., asthmatics, COPD patients) is a central mechanism by which particles cause lung disease, primarily from organic dusts (Pickrell *et al.*, 2009, 2010). Metal oxide nanoparticles may also have direct cytotoxic effects in lung cells. After intratracheal instillation, ultrafine colloidal silica (UFCS) particles had greater ability to induce tissue damage and inflammation compared to fine colloidal silica (FCS) particles. Electron microscopy demonstrated UFCS and FCS particles on both bronchiolar and alveolar wall surfaces; type I epithelial cell necrosis and basement membrane damage was greater in UFCS than FCS particles (Kaemawatawong *et al.*, 2005).

Inhalation of highly insoluble ultrafine particles (diameter 20 nm) of low intrinsic toxicity (TiO<sub>2</sub>) resulted in pulmonary inflammatory responses. However, these effects were not acute and occurred only after prolonged inhalation exposure of the aggregated ultrafine particles at high levels >1 milligram/m<sup>3</sup> (Oberdörster *et al.*, 1995). Ultrafine carbon particles are more toxic on an equal mass basis than fine carbon particles, but this is not true if they are examined on a total surface area basis (Oberdörster *et al.*, 2010).

### Carbon nanotubes

Pharyngeal aspiration of single-walled carbon nanotubes (SCWNT) elicited an acute pulmonary inflammation in C57BL/6 mice that progressed to fibrosis and granulomas (Shvedova *et al.*, 2005). SWCNT caused a dose-dependent release of protein, LDH and gamma-glutamyl transferase activities into bronchoalveolar lung washings (lavage). In addition, elevated 4-hydroxynonenal (oxidative biomarker), depleted glutathione in lungs, leukocyte accumulations and cytokines were present in lavage fluids at days 1–7. This was followed by fibrogenic transforming growth factor (TGF-β1) that peaked on day 7. The progressive fibrosis found in mice exhibited two distinct morphologies – SWCNT-induced granulomas, and diffuse interstitial fibrosis and alveolar wall thickening. Functional respiratory deficiencies and decreased bacterial clearance (*Listeria monocytogenes*) were found in mice treated with SWCNT (Shvedova *et al.*, 2005). *In vitro* exposures of multiwalled carbon nanotubes to fibroblasts at high doses induce a similar inflammation (Ding *et al.*, 2005). Equal doses of ultrafine carbon black particles or fine crystalline silica (SiO<sub>2</sub>) did not cause either

granulomas or alveolar wall thickening. Instead, they caused weaker pulmonary inflammation and damage. Inhalation of multiwalled carbon nanotubes induced no lung changes, but marginal pulmonary and systemic immunosuppression was observed (Mitchell *et al.*, 2007).

### Intranasal exposure

High doses of carbon black, given intranasally, showed adjuvant activity as indicated by enlargement of peribronchial lymph nodes and ovalbumin-specific production of thymocyte (Th) 2 specific interleukin (IL)-4, IL-5 and IL-10. Local cytokine production after carbon black exposure is predictive of allergic airway inflammation (De Haar *et al.*, 2005).

### Inhalation exposure

Both particle size and solubility are important determinants of biological response after lung exposure. If cleared rapidly they will be less injurious; if not they will remain as a chronic irritating source (Pickrell *et al.*, 2004, 2009). Particles must be small enough to be inhaled into deep lung – usually taken to be  $\leq 4\mu\text{m}$  (4000nm). Particles between 4000nm and 500nm will be phagocytized and cleared rapidly. Particles  $<500\text{nm}$  aggregate size will be less efficiently phagocytized by phagocytes and may translocate to the pulmonary interstitium and remain there for relatively long periods of time. For example, in a recent study of fullerene particles with a geometric mean diameter of 96nm (based on number) in rat lungs, it was estimated that  $>99\%$  of particles remaining in the lung 6 months after exposure were in the interstitium, while particles that did not enter the interstitium were cleared by alveolar macrophages relatively rapidly with a half-life of 15–24 days (Shinohara *et al.*, 2010).

Thermodegradation products of polytetrafluoroethylene (PTFE) contain singlet ultrafine particles (median diameter 26nm); the fumes are toxic to rats at inhaled concentrations of  $0.7\text{--}1.0 \times 10^6$  particles/ $\text{cm}^3$ . Inhalation studies with ultrafine particles ( $\leq 100\text{nm}$ ; NP) in rats suggest that particles  $\leq 50\text{nm}$  in diameter may contribute to increased mortality and morbidity. Inhalation exposure in rats caused an acute hemorrhagic pulmonary inflammation and death after 10–30min (Oberdörster *et al.*, 1995). These results confirmed reports from other laboratories that the toxicity of PTFE fumes should not be attributed only to gas-phase components of these fumes. Aging of PTFE fumes with concomitant aggregation of the ultrafine particles greatly decreases their toxicity.

Fumes from overheated Teflon<sup>TM</sup> (PTFE)-coated frying pans cause a fatal hemorrhagic pneumonitis in caged

birds directly adjacent in both time and space to the overheating (Blandford *et al.*, 1975). Birds appear to be more sensitive than rats and humans to direct inhalation of Teflon<sup>TM</sup> fumes from overheated skillets; this sensitivity probably reflects their physiologically more efficient respiratory system. When birds are removed from the overheating event by a short period of time, or when birds are in an adjacent room, there is a comparatively minimal reaction. Current understanding implies that the small particles released from heated PTFE rapidly condense into larger and less biologically potent particles (Lee and Seidel, 1991). Aged particles collected as agglomerates were not toxic when given intratracheally to rats, but the particles became toxic when rats were given inhalation exposure to fumes evolved from the reheated agglomerate. Rats died with pulmonary edema and hemorrhage reflecting Type I pneumocyte damage.

## EPIDEMIOLOGICAL DATA

Epidemiological studies show an association between particulate air pollution and acute mortality and morbidity down to ambient particle concentrations below 100 micrograms/ $\text{m}^3$ . Whether this association also indicates causality between acute health effects and particle exposure at these low levels is still unclear, but several examples of associations between particulate air pollution and adverse health effects are available, and it suggests a high probability that a cause and effect relationship exists.

### Sulfur dioxide (oxides of sulfur particles)

Sulfur dioxide (oxide of sulfur particles) comes mainly from burning sulfur-containing fuels (Sullivan *et al.*, 2006), causing both indoor and outdoor pollution. For example, poorly ventilated kerosene space heaters are sources of indoor sulfur dioxide. Sulfur dioxide particles are hygroscopic and tend to grow larger with increasing hydration of the atmosphere.

Nasal breathing filters out much of the inhaled sulfur dioxide; it is water soluble and is often absorbed in the upper portion of the respiratory tract (Sullivan *et al.*, 2006). Sulfur dioxide is irritating to the eyes, nose and airways, and its odor is detected at concentrations as low as 0.5ppm. At  $>6\text{ppm}$ , companion animals often show acute clinical signs including tearing, runny nose, cough, bronchospasm and shortness of breath. Additional chronic signs that come from prolonged exposure at lower exposure concentrations include cough, mucus hypersecretion and frequent clearing of the throat; these reflect airway inflammation and chronic bronchitis. Massive exposure is capable of inducing severe,

permanent pulmonary damage. Low-level prolonged human exposures correlate well with bronchial asthma.

### Swine barn dust exposure

Gases and/or ultrafine particles in swine barns can be important factors in the development of increased bronchial responsiveness both in animals and their human caretakers. For example, healthy human volunteers weighing pigs for three hours developed a neutrophilic pneumonitis, and they had an increased bronchial responsiveness to methacholine. Wearing a mask reduced, but did not abolish, the inflammatory response (Larsson *et al.*, 2002). *In vitro* data suggest that airway epithelial cell swine dust extract exposure enhances subsequent lymphocyte adhesion to epithelial cells by a modulation of the expression of intracellular adhesion molecule 1, and protein kinase C alpha (Mathisen *et al.*, 2004). The associated inflammation is characterized by increased numbers of neutrophils, macrophages and lymphocytes to a lesser degree, in pigs and their caretakers. The inflammation is associated with increased IL-6 in cultured cells, suggesting an asthma-like reaction (Pickrell *et al.*, 2010). Interestingly, this inflammation is most pronounced in caretakers with no prior exposure to this environment, which suggests a tolerance to endotoxin or other substances in this environment associated with repeated exposures (Von Essen and Romberger, 2003).

### Nanoparticles exposure in the home

Environmental tobacco smoke (ETS) is a health risk for companion animals. It is a major source of indoor particles, and can release more than 4000 potential toxicants into the air (Sullivan *et al.*, 2006). While the effects of smoke inhalation may be mostly due to toxic gases (e.g., carbon monoxide), ETS particles, such as acrolein, are capable of producing pulmonary damage (Fitzgerald and Vera, 2006). Frequently observed signs include wheezing, chronic cough, chronic hyperreactive airways and chronic bronchitis. Water soluble toxins are absorbed and injure mostly the upper respiratory tract, while less soluble materials go deeper into the lungs and injure the pulmonary parenchyma. The EPA has classified ETS a group A carcinogen, meaning that there is sufficient evidence to indicate that it will produce cancer in humans (Sullivan *et al.*, 2006). Epidemiological evidence in humans demonstrates a strong relationship between ETS and cancer. Mice exposed to ETS experimentally at high doses developed increased incidences of cancer (Hecht, 2005). Although most investigators continue to compare experimental results in animals with human data, most animals appear to be less sensitive than man

(Coggins, 2002). Beta-carotene supplementation attenuated cardiac remodeling induced by 1-month's tobacco smoke exposure in rats (Zornoff *et al.*, 2006). After 1-month's exposure to ETS, cardiac remodeling was present as indicated by disorganization or loss of myofilaments, in plasma membrane folding, dilatation of the sarcoplasmic reticulum and polymorphic mitochondria with swollen or decreased cristae. Rats given beta-carotene during cigarette smoke exposure had minimal or no significant cardiac remodeling. These data suggest beta-carotene attenuates, reduces or minimizes cardiac remodeling induced by cigarette smoke. These data are probably most relevant to obese cardiac-compromised companion animals. Differential diagnoses or conditions which must be adequately distinguished from smoke inhalation include asthma, heart disease, allergic pulmonary disease, inhalation of toxic solvents or sprays, pneumonia, neoplasia, trauma, chronic obstructive pulmonary disease (COPD) and pneumothorax (Fitzgerald and Vera, 2006).

Household use of metal oxide ENMs in sunscreens (mostly zinc oxide or titanium dioxide), or as cosmetics, has not led to reports of toxicities in humans (Nel *et al.*, 2006). Other metal oxide ENMs such as ferric oxide, however, are cytotoxic to mesothelioma cells and fibroblasts *in vitro* (Brunner *et al.*, 2006). In comparison, zinc oxide fumes at high doses (500 µg/m<sup>3</sup>), in an occupational setting, cause fume fever (fatigue, chills, fever, myalgia, cough and leukocytosis) (Nel *et al.*, 2006).

### Dog exposures to automobile exhaust aerosols

Repeated, high exposures to the complex pollutant mixtures in automobile exhaust aerosols cause lung structural changes induced by sustained inflammatory processes resulting in airway and vascular remodeling and altered repair. These exposures are complicated by a heavy load of oxidant gases. Bronchoalveolar lavage from dogs in heavily exhaust-polluted environments shows increased numbers of activated alveolar macrophages in association with ultrafine particles in alveolar type I and II cells. Cytokines released from both circulating inflammatory cells and resident lung cells, in response to endothelial and epithelial injury, are thought to play important roles. The lung changes are typically associated with myocardial and endothelial pathology (Calderon-Garciduenas *et al.*, 2001a, b).

## EMERGING CHALLENGES

A question that received recent scientific scrutiny is the potential indirect impact that ENMs may have as

contaminant carriers. For example, the uptake of phenanthrene by daphnids is increased by C<sub>60</sub> nanoparticles, and it increases phenanthrene toxicity to algae. Effects on uptake and toxicity are, however, variable depending on the organism and the toxicant (Baun *et al.*, 2008). The significance of these observations is still unclear, but it indicates that the possibility of ENMs affecting the potency and/or kinetics of toxicant co-exposures should be considered. On the other hand, ENMs can be used to reduce the impacts of environmental contaminants. Iron (0 valence/charge) particles, for example, may be used to remove chromium and lead in drinking water (Iseli *et al.*, 2009).

Evidence of ecotoxicological effects associated with nanomaterials is emerging. For example, leachates from low-purity fullerenes were shown to be toxic to aquatic organisms (Hull *et al.*, 2009). Nanotechnology may lead to novel types of pollutant effects. Organisms may not have the ability to metabolize and detoxify ENMs using pathways evolved to prevent poisoning from chemicals in solution. The diversity of environmental conditions and possible ecological impacts pose additional challenges to ecotoxicological risk assessment. Data from diverse test organisms are needed, and a general scarcity of data is still a major concern (Cattaneo *et al.*, 2009).

# Ionizing radiation and radioactive materials in health and disease

*R. Victor Rebois and Kausik Ray*

## INTRODUCTION

Ionizing radiation consists of electromagnetic waves or atomic particles with the capacity to strike an electron with sufficient force to strip it from its atom thus creating an ion. Ionizing radiation can also generate highly reactive nonionic species known as free radicals. However, ionizing radiation cannot be detected, even at lethal levels, without instruments designed for the purpose. Ionizing radiation is produced when nuclear weapons are detonated and when chest X-rays are taken. We are exposed to ionizing radiation all our lives and it may have beneficial or detrimental consequences. The objectives of this chapter are to describe common types of ionizing radiation from both natural and man-made sources, discuss how they are detected and measured, consider their uses especially in medical diagnosis and treatments, and provide information on both the possible health benefits and risks associated with ionizing radiation. All of the topics covered herein are treated more extensively in a concise, interesting, highly informative and well-written book ([Henriksen and Maillie, 2003](#)) that is highly recommended for those interested in a more in-depth look at this subject.

Roentgen, Henri Becquerel and Marie and Pierre Curie just before the turn of the 20th century. Wilhelm Roentgen discovered a form of penetrating radiation on November 8, 1895 when he observed that an electric discharge tube covered with black paper caused a dye outside the tube to fluoresce. Although the term Roentgen rays is used in many countries, the more common term for these electromagnetic waves is the name given to them by Roentgen himself, X-rays.

Henri Becquerel discovered radioactivity in the spring of 1896, when a photographic plate protected from visible light was exposed to a uranium salt. In July of 1898 Marie and Pierre Curie published their findings regarding the isolation of a new compound that they suggested be named polonium after Marie Curie's homeland of Poland. In this publication, they use the term radioactivity for the first time to describe the properties of the newly discovered element. A few months later, they published on another newly discovered radioactive element that they named radium. Marie Curie died in 1934 at the age of 67 from a blood disease, possibly leukemia, which may have been the result of her work with radioactive substances.

## TYPES OF IONIZING RADIATION

## HISTORICAL PERSPECTIVE

Our understanding of ionizing radiation began with the pioneering work of individuals like Wilhelm Conrad

The nucleus of an atom contains one or more protons and, with the exception of hydrogen, neutrons, while any associated electrons, frequently equal in number to the protons, move about the nucleus in specific orbitals.

TABLE 25.1 Naturally occurring radioactive families

Series	Half-life of parent (years)	Parent radioisotope	Stable decay product
Thorium	$1.41 \times 10^{10}$	Th-232	Pb-208
Uranium–radium	$4.47 \times 10^9$	U-238	Pb-206
Uranium–actinium	$7.04 \times 10^8$	U-235	Pb-207
Neptunium	$2.14 \times 10^6$	Np-237	Bi-209

Each element is defined by the number of protons in the nucleus, its atomic number ( $Z$ ),  $Z = 1$  for hydrogen,  $Z = 6$  for carbon,  $Z = 8$  for oxygen, etc. Although the number of protons defines the element, the number of neutrons defines the different isotope of that element. For example, hydrogen has no neutrons in its nucleus, but there are two additional isotopes of hydrogen, deuterium with one neutron and tritium which contains two neutrons. The atomic mass of an isotope is determined by the total number of nucleons (protons and neutrons). Electrons with a mass that is  $1/1838$ th that of a proton or neutron contributing little to the total atomic mass. The shorthand for hydrogen, deuterium and tritium, is  $^1\text{H}$ ,  $^2\text{H}$  and  $^3\text{H}$  (or H-1, H-2 and H-3), respectively. Most isotopes are stable, that is to say the number of protons and neutrons remains unchanged indefinitely, but some isotopes have unstable nuclei making them radioactive. For example, hydrogen and deuterium are stable isotopes while tritium is a radioactive isotope that is commonly used in biomedical research.

Radioactive isotopes go through a process of radioactive decay that involves emitting ionizing radiation in the form of subatomic particles and/or electromagnetic radiation. The source of radiation is the nucleus, and the decay continues until the nucleus is converted to a stable isotope. Tritium decays by emitting only one particle, becoming a stable isotope of helium (He-3 as opposed to the more common form of helium He-4), while uranium (U-238) emits a total of 14 particles before becoming a stable isotope of lead (Pb-206). There are four naturally occurring radioactive families on earth. Two of these have almost disappeared because their half-lives are relatively short in comparison to the age of the earth (Table 25.1) leaving only the thorium and the uranium–radium series.

Each decay event on the way to becoming a stable isotope is known as a disintegration and the rate of decay is given in disintegrations per minute (DPM) or disintegrations per second (becquerels abbreviated Bq). The particles emitted during radioactive decay include alpha and beta particles and neutrons. In addition to ionizing particles, radioactive decay can also produce a form of ionizing short wave electromagnetic radiation known as gamma rays. Important information about the steps involved in the decay of a radioactive isotope

FIGURE 25.1 Decay scheme for radioactive I-131 showing beta particle emissions leading to the formation of a stable isotope of xenon (Xe-131). The decay occurs in two ways, 7.24% of the time a beta particle with maximum energy of 334 keV is emitted with the subsequent emission of a 637 keV gamma ray, and 89.9% of the time the decay occurs by the emission of a beta particle with a maximum energy of 606 keV and the subsequent emission of a 364 keV gamma ray.

is contained in its decay scheme. An example for iodine (I-131), an important radioisotope with regard to nuclear power plant accidents, is given in Figure 25.1.

Ionizing radiation can also originate from outside the atomic nucleus. Examples include X-rays and extreme ultraviolet radiation. Other atomic particles qualifying as ionizing radiation, but not considered here, include a variety of particles generated in particle accelerators and particles, other than alpha and beta particles, produced in nuclear fission and fusion reactions.

## Alpha and beta particles

Historically it was observed that radioisotopes emitted radiation that could be divided into three different types according to the way it behaved when subjected to a magnetic field. Two of them followed a curved path in a magnetic field, but in opposite directions indicating that they had opposite charges. The positively charged radiation was called alpha rays while the negatively charged radiation was referred to as beta rays. The third type of radiation was not deflected by a magnetic field and was referred to as gamma rays. In 1903, Ernest Rutherford discovered that alpha particles were equivalent to a helium nucleus consisting of two protons and two neutrons and having a charge of +2. Beta particles have the mass ( $9.1 \times 10^{-31}$  kg) and the negative charge ( $1.6 \times 10^{-19}$  coulombs) of an electron (see Table 25.2 for a list of units and magnitudes). Particles with the same mass and a charge opposite in sign but equal in magnitude to an electron are called positrons, and may also be referred to as beta particles. The kinetic energy imparted

R	roentgen
rad	radiation absorbed dose
rem	roentgen equivalent in man (or mammals)
sec	seconds
Sv	sievert
<b>Magnitudes</b>	
a	atto ( $10^{-18}$ )
f	femto ( $10^{-15}$ )
p	pico ( $10^{-12}$ )
n	nano ( $10^{-9}$ )
$\mu$	micro ( $10^{-6}$ )
m	milli ( $10^{-3}$ )
c	centi ( $10^{-2}$ )
k	kilo ( $10^3$ )
M	mega or million ( $10^6$ )
G	giga ( $10^9$ )
T	tera ( $10^{12}$ )
P	peta ( $10^{15}$ )
E	exa ( $10^{18}$ )

to non-relativistic alpha and beta particles when they are ejected from the nucleus is given by the formula:

$$E = \frac{1}{2}mv^2$$

where  $E$  is the energy of the particle in joules,  $m$  is its mass in kg and  $v$  its velocity in m/sec. The unit of energy for this equation is the joule (J), but the energy of ionizing particles is usually given in electron volts (eV). One eV is the amount of energy imparted to an electron when it is accelerated by a potential difference of one volt. The factor for converting joules ( $\text{kg}\cdot\text{m}^2/\text{sec}^2$ ) to eV is:

$$1 \text{ eV} = 1 \text{ V} \times 1.6 \times 10^{-19} \text{ C} = 1.6 \times 10^{-19} \text{ J}$$

Ionizing particles have energies in the thousands (keV) or millions of electron volts (MeV):

$$1 \text{ KeV} = 1 \text{ eV} \times 10^3 \text{ and } 1 \text{ MeV} = 1 \text{ eV} \times 10^6$$

Alpha particles emitted by a particular radioisotope all have the same energy. For example, U-238 emits an alpha particle with an initial energy of 4.19 MeV, but there is variation in the energies of alpha particles from different isotopes. The energy of alpha particles ranges from 3 to 7 MeV while beta particles have energies

TABLE 25.3 Spectral ranges for X-rays and gamma rays

Radiation	Wavelength (nm)	Frequency ( $\text{sec}^{-1}$ or hertz)	Energy (keV)
Soft X-rays	10–0.1	$3 \times 10^{16}$ – $3 \times 10^{18}$	0.12–12
Hard X-rays	0.1–0.01	$3 \times 10^{18}$ – $3 \times 10^{19}$	12–120
Gamma rays, high energy X-rays	<0.01	$>3 \times 10^{19}$	>120

ranging from 20 keV to a few MeV. Beta particles from the same isotopic source vary in their energy. The value given in decay schemes represents the maximum energy (Figure 25.1). As a rule of thumb, the average energy is 1/3 of the maximum. The additional energy lost when lower energy beta particles are emitted is contained in a neutrino that is also emitted.

### Gamma rays

The wave length ( $\lambda$ ) of electromagnetic radiation varies from more than  $10^8$  meters in length to less than  $10^{-16}$  meters. The energy of electromagnetic waves is given by the equation:

$$E = hc/\lambda$$

where  $h$  is Planck's constant ( $6.626 \times 10^{-34} \text{ J}\cdot\text{s}$  or  $4.136 \times 10^{-15} \text{ eV}\cdot\text{s}$ ) and  $c$  is the speed of light ( $3.0 \times 10^8$  meters/sec). Only electromagnetic waves with  $\lambda$  of less than approximately  $10^{-8}$  meters have sufficient energy to qualify as ionizing radiation. Electromagnetic radiation with  $\lambda$  between  $1.2 \times 10^{-7}$  and  $10^{-8}$  meters are referred to as extreme ultraviolet (EUV) rays while X-rays generally range from  $10^{-8}$  to  $10^{-11}$  meters and gamma rays are any electromagnetic radiation with  $\lambda$  of less than  $10^{-11}$  meters (Table 25.3).

Plugging these values into the preceding equation give a range of energy of 0.01–0.12 keV for EUV, 0.12–120 keV for X-rays and  $>120$  keV for gamma rays.

Electromagnetic radiation interacts with matter in three ways: (1) the photoelectric effect, (2) Compton scattering and (3) pair formation. The photoelectric effect results in the complete absorption of a gamma photon's energy by an electron in the inner K and L shells of an atom. The electron escapes with energy ( $E_e$ ) approximately equal to that of the photon ( $E_\gamma$ ) less the binding energy of the electron ( $E_b$ ):

$$E_e = E_\gamma - E_b$$

$E_b$  varies with the atomic number ( $Z$ ) but is generally much less than  $E_\gamma$  so that the energy carried away by the electron is close to that of the incident gamma photon. Gamma photons can also be scattered by an encounter

with an electron. This is known as Compton scattering and results in the deflected gamma photon continuing in a new direction with reduced energy while the electron carries off the balance of the energy in another direction. Pair formation occurs when a gamma photon is converted into an electron–positron pair. The energy represented by an electron (or positron) with resting mass  $m_0$  ( $9.1 \times 10^{-31}$  kg) is given by  $m_0c^2$ . Since  $c = 3 \times 10^8$  m/sec and  $1 \text{ MeV} = 1.6 \times 10^{-13}$  J ( $\text{kg}\cdot\text{m}^2/\text{sec}^2$ ):

$$m_0c^2 = 0.51 \text{ MeV}$$

Because both an electron and a positron are formed the photon's energy must be at least 1.02 MeV. Any energy in excess of this amount is shared by the particles as kinetic energy. Positrons are unstable and after coming to rest will quickly recombine with resting electrons producing a pair of gamma photons each of 0.51 MeV and moving in opposite directions.

## X-rays

When a beam of electrons hits a heavy metal target, their rapid deceleration by positively charged atomic nuclei within the target, causes some of the electrons energy to be converted to electromagnetic radiation in the form of X-rays. Radiation produced in this way is also known as bremsstrahlung. The beam of electrons originates at the negatively charged cathode within an evacuated tube and is accelerated toward the metal target (the anode) by a voltage difference between the two electrodes. The energy of the X-rays depends upon the magnitude of this voltage difference. X-rays generated by voltage differences of 100 to 300 kV have enough energy to ionize molecules in the target tissue by Compton scattering. The electrons that are stripped from molecules are known as secondary electrons, and if they have sufficient energy to produce additional ionizations, then they are known as delta rays. X-rays produced with high voltages have important diagnostic and therapeutic applications. The energy of X-rays produced by X-ray tubes is limited by the potential difference that can be applied to the electrodes. The practical limit for conventional X-ray tubes is 300 kV. By definition the electrons produced by this voltage would have a maximum energy of 300 keV and are capable of producing X-rays with the same maximum energy. Only about 1% of the electrons striking the anode generate X-rays, and their average energy is 1/3 of the maximum. The energy of the remainder of the electrons is converted to heat. Generating X-rays with energies on the order of 10 MeV requires a linear accelerator. An X-ray with energy of 10 MeV would correspond to a wavelength on the order of  $10^{-13}$  m or 0.0001 nm. This overlaps extensively with

gamma rays (Table 25.3). What distinguishes gamma rays from X-rays is not wavelength but the source of the radiation. Gamma rays originate in the nucleus of an atom while X-rays arise from sources outside the nucleus.

X-ray tube voltages between 25 and 50 kV are used to generate “soft” X-rays (Table 25.3) which are absorbed completely after producing a single ionization by the photoelectric effect described above. Soft X-rays are important for medical diagnostic procedures such as mammography because they produce better contrast between tissues that do not differ greatly in electron density making it easier to distinguish between tumor tissue and normal tissue.

## MEASURING IONIZING RADIATION

Almost everyone has experienced a sun burn and understands that there is a correlation between the dose of ultraviolet radiation received from the sun and skin redness. Originally, skin reddening following exposure to ionizing radiation was used to measure the absorbed dose and was known as the skin erythema dose. There are obvious drawbacks to this method of measuring dose. Redness caused by a given dose is going to vary with the individual making it a qualitative rather than a quantitative measure of exposure. There is a delay before the dose can be assessed and the method also lacks sensitivity. The erythema dose was replaced by the roentgen (R) unit which is equivalent to the amount of X-rays or gamma rays that generate  $2.58 \times 10^{-4}$  coulombs of ions/kg of air. In 1953, the radiation absorbed dose (rad) was adopted which is equal to the amount of radiation which yields an energy absorption of 100 erg/g (i.e.  $10^{-2}$  joules/kg). Although the rad is still commonly used, it is being replaced by the Système International (SI) unit known as the gray (Gy), named after the radiation biologist L. Harold Gray. The relationship between R, rad and Gy is given in Table 25.4.

The amount of energy deposited as ionizing radiation travels through tissue is known as the linear energy transfer (LET) and is given in  $\text{keV}\cdot\mu\text{m}^{-1}$ . Alpha particles do not travel very far, only a few centimeters in air and less than a millimeter in water or soft tissue. They are stopped by clothing or the first few cells of the skin but the LET for these particles is very high compared with other forms of radiation and most of the energy is deposited near the end of its track producing a peak called the Bragg peak (Figure 25.2).

By comparison, beta particles of 1 MeV will penetrate to about 0.5 centimeters in water or soft tissue, and have a much lower LET. Damage to tissue is related to LET.

TABLE 25.4 Units used to measure the activity of a source (Bq) and radiation doses (Gy and Sv)

SI unit	Dimensions	Other units	Equivalencies
Becquerel (Bq)	Disintegrations/sec (DPS)	Curie (Ci)	$37 \times 10^9 \text{ Bq} = 1 \text{ Ci}$
Gray (Gy)	J/kg	Roentgen (R) = $2.58 \times 10^{-4} \text{ Ci/kg ions}$	$1 \text{ Gy} \approx 108 \text{ R}$ (for gamma rays in soft tissue)
		Radiation absorbed dose (rad) = $100 \text{ erg/g}$	$1 \text{ Gy} = 100 \text{ rad}$
Sievert (Sv)	J/kg	Roentgen equivalent in mammals (rem)	$1 \text{ Sv} = 100 \text{ rem}$

FIGURE 25.2 Bragg curve for the deposition of energy by an alpha particle along its track in air.

Absorbed dose in Gy does not take into account disparities in the ability of different types of radiation to cause tissue damage. Therefore another unit of measure known as the equivalent dose was established. Originally, the units were known as roentgen equivalent in man (or mammals), abbreviated rem. The SI unit for equivalent dose is the sievert (Sv) named after the Swedish scientist Rolf M. Sievert, and its relationship to the absorbed dose is given by the equation:

$$\text{Sv} = w_R \cdot \text{Gy}$$

where  $w_R$  is the radiation weighting factor for a particular type of radiation, and is proportional to its LET. The relationship between rem and Sv is given in Table 25.4. X-rays and gamma rays have a low LET depositing energy at a low rate along their track often emerging from the body and continuing on their way. This is the reason why X-rays can be used to generate images on a photographic plate. X-rays pass through soft tissue and reach the film placed opposite that part of the body being X-rayed. When the film is developed, areas that were exposed to X-rays appear dark. Dense tissues such as bone absorb most of the X-rays producing, in essence, a shadow on the film that is revealed by lighter areas on the developed film. Since the LET for X-rays, as well as gamma rays, is the lowest for ionizing radiation their  $w_R$  value is set at one. In contrast, the alpha particles emitted by a source that is in direct contact with tissue

TABLE 25.5 Weighting factors for various types of ionizing radiation used for converting absorbed dose in Gy to equivalent dose in Sv

Type of ionizing radiation	$w_R$
X-rays, gamma rays, beta particles	1
Protons >2 MeV	2
Neutrons	5
<10 keV	
10 keV–100 keV	10
100 keV–2 MeV	20
2 MeV–20 MeV	10
>20 MeV	5
Alpha particles, nuclear fission products	20

deposit all of their energy in the tissue over the space of a few millimeters, hence they have a high LET and are assigned a  $w_R$  value of 20. The values of  $w_R$  have been arrived at experimentally but are nonetheless difficult to determine quantitatively, which is one reason why accessing the equivalent dose can be difficult. Values of  $w_R$  are given in Table 25.5. Complicating matters is the fact that different organs vary in their sensitivity to the effects of radiation. This is taken into account by using a tissue weighting factor which varies for different organs. The weighting factor is highest for more sensitive organs and the sum of the weighting factors for all organs is 1.0. Gonads are considered the most sensitive and are given a weighting factor of 0.20, while skin ranks at the bottom with a weighting factor of 0.01 (Henriksen and Maillie, 2003). Multiplying the weighting factor by the equivalent dose gives what is known as the effective equivalent dose for a given organ. In the case of whole body irradiation, the weighting factor is, of course, 1.0, so equivalent dose is equal to the effective equivalent dose.

## DEVICES FOR MEASURING IONIZING RADIATION

Devices used for detecting and measuring the amount (Bq) and energy (MeV) of radiation and for estimates of the absorbed or equivalent dose (Gy or Sv) take advantage of the ability of radiation to cause ionization. These devices are treated summarily here. Much more detail can be found elsewhere (Delaney and Finch, 1992) for

those who are interested. These devices can be divided into two categories; those that store information about radiation exposure with the information requiring retrieval at some later time, and those that are able to detect radiation as it occurs.

## Film

Photographic film is sensitive to ionizing radiation just as it is to light. The film emulsion contains crystals of silver halide, usually silver bromide. In essence, ionizing radiation facilitates the transfer of electrons from the bromide ions to silver ions producing grains of elemental silver. With increasing exposure, the film becomes progressively more opaque as more and more silver grains are deposited until the film finally appears black when developed. Thus, the amount of silver deposited is related to the dose of radiation received. The film is inserted into a film badge holder and clipped to a worker's clothes serving as a personal dosimeter. Portions of the film can be covered with different materials in order to gain information about the type of exposure an individual receives. For example, film behind a cadmium plate will be more highly exposed than the unmasked portion of the film if the dosimeter is exposed to low energy neutrons. Filters may also be used on part of the film to distinguish between exposure to beta and gamma radiation.

## Thermoluminescent dosimeter

Thermal luminescence dosimeters (TLD) are composed of lithium fluoride (LiF) crystals. When these crystals are exposed to radiation, electrons become trapped in the excited state. When the crystal is heated to approximately 200°C these electrons give up their excess energy emitting photons in proportion to the amount of radiation absorbed. TLD make good dosimeters because they mimic the properties of tissue with regard to absorption of radiation. They have advantages over film in that no film development is required and they can be reused many times. The disadvantages are that the information stored in the TLD can only be retrieved once, and TLDs do not reveal as much information about the types of radiation exposure as film can.

## Gas-filled detectors

Pulse ionization detectors have a gas-filled chamber containing two electrodes to which a voltage is applied in order to generate an electrical field. Ionizing radiation enters the chamber through a window in the detector and ionizes gas within the detector, typically a mixture of 90% argon and 10% methane. The electrons from the

ionization are attracted to the anode while the positively charged cations are drawn to the negatively charged cathode. Arrival of these ions at the electrodes causes a voltage change that can be detected. Since the energy of an individual particle or photon determines how many ionizations it can cause, the number of ions arriving at the electrodes, and hence the voltage change, will be proportional to the energy of the radiation being detected. The energy spectrum reveals information about the type of radiation and can be used to identify the source. However, an accurate determination of the energy of a particle or photon depends upon all of its energy being deposited in the gas within the chamber. This is not a problem with alpha particles which travel only a few centimeters in a gas before giving up all of their energy. In this case, the primary concern is admitting the alpha particles through the detector window. Windowless detectors exist which require that a flow of gas be maintained in order to preserve the environment between the electrodes. In contrast, high energy beta particles and gamma radiation will emerge from a detector of reasonable dimension before they have given up all of their energy so that an accurate energy spectrum cannot be obtained.

If the voltage applied to the electrodes is increased, the ions produced by the radiation entering the detector will be accelerated toward the electrodes, giving them enough energy to ionize additional molecules and atoms. There is a range of voltage in which the increased number of ions produced is proportional to the energy of the particle of ionizing radiation. Detectors known as proportional counters operate in this voltage range. These detectors have higher sensitivity than the pulse ionization detectors discussed at the outset of this section. The time required to register the voltage change associated with a single particle is on the order of a few  $\mu\text{sec}$ . Thus, individual events can be resolved even at a relatively high rate of incidence allowing a determination of the number of decays per unit time for a particular source.

If the electrode voltage is increased above the proportional range, the ionizing radiation initiates a cascade of ionizations, and the resulting voltage change recorded by the instrument is independent of the original particle's energy. These electrode voltages are in the Geiger-Muller range and are used in Geiger counters. The advantages of these instruments are that they are inexpensive to manufacture and sensitive, which makes it easy to detect low energy radiation. A disadvantage is that they do not give any information about the energy of the particles being measured and their design prevents them from being able to accurately measure dose rates much in excess of 50 Bq. As with other gas-filled detectors, Geiger counters are capable of detecting low to moderate energy beta particles and some alpha particles but are not very useful for high energy beta particles and can only detect 1–2% of incident gamma radiation.

## Scintillation counters

Scintillators are materials that emit light (usually ranging from visible blue to near ultraviolet) in response to ionizing radiation. Scintillation counts have a photomultiplier tube that generates an electrical pulse which is proportional to the amount of light produced by the scintillator. Scintillators can be organic compounds such as molecules containing benzene rings or inorganic compounds such as crystals of sodium iodide containing traces of thallium – otherwise written as NaI(Tl). Crystals on account of their density are ideal for stopping gamma and X-rays, forcing them to give up all of their energy to the crystal. Organic scintillators can be dissolved in liquids which also have good X-ray and gamma ray stopping power. In scintillation counting the ions produced by the incident radiation subsequently excite electrons associated with the scintillator. Light is produced when these excited electrons return to the ground state. The number of scintillators that are excited, and consequently the amount of light emitted, is proportional to the energy of the ions produced by the radiation. As discussed above, electromagnetic waves interact with matter in several different ways, one of these being by the photoelectric effect. Since the photoelectric effect generates a photoelectron whose energy is nearly equal to that of the original photon, the amount of light produced when the photoelectron excites the scintillator is a function of the original photon's energy and produces what is known as the photopeak in the energy spectrum. The photopeak is characteristic of the emitter making it feasible to identify the isotope that produced it. An example is shown in Figure 25.3. Compton scattering also contributes to the energy spectrum and is broadly distributed as energies up to two thirds that of the photopeak. The reason is that the electrons produced by Compton scattering are of varying and lesser energy compared with the photoelectrons. The contribution of Compton scattering can also be seen in Figure 25.3. Beta particles also produce photopeaks that reveal information about their energy. Depending on the scintillator, alpha particles produce between 10 and 100% of the light that is produced by an electron or beta particle with equivalent energy. In addition to measuring the energy of ionizing radiation, scintillation counters measure the event rate with resolution in the  $\mu\text{sec}$  range making it possible to accurately measure the Bq for sources with relatively high rates of decay.

## Semiconductor detectors

When a voltage is applied to a pair of electrodes bridged by an ideal semiconductor no current flow is induced by the electrical field. Ionizing radiation can transfer energy to electrons within the semiconductor making

**FIGURE 25.3** Energy spectrum for Co-60 determined with an NaI(Tl) scintillation detector and with a germanium semiconductor detector. Two photopeaks are observed corresponding to gamma radiation with energies of 1.17 and 1.33 MeV.

them susceptible to the electric field so that they drift in the direction of the anode while the electron's counterpart, referred to as a hole, behaves like a positively charged ion and drifts in the opposite direction toward the cathode. This movement of ions induces a current that can be measured. The principle of operation is similar to that of gas-filled detectors, and semiconductor detectors produce analogous energy spectra useful for fingerprinting the source. Of significance is the fact that in gas-filled detectors and scintillators, approximately 25 and 100 eV are required, respectively, to produce a single ionization, whereas in operational semiconductor detectors only 3 eV is needed to produce an electron-hole pair. This disparity means that semiconductor detectors produce energy spectra with higher resolution than do gas-filled detectors or scintillation counters as can be seen from looking at Figure 25.3. The reason for this is that an ionizing particle will produce many more electron-hole pairs in a semiconductor than it does ion pairs in a gas-filled detector or scintillation counter, thus reducing the statistical variation for semiconductors compared with the other types of detectors. Another advantage of semiconductor detectors is that the stopping time for ionizing radiation in these detectors is very short, and consequently the period during which detection takes place is correspondingly short. As a result, the time resolution of these detectors is in the nanosecond range enabling these detectors to record very high dose rates. A disadvantage of semiconductor detectors, which are made of silicone or germanium, is that they are not ideal semiconductors. When an electrical field is applied to these detectors, a

current flow is created that constitutes a background of sufficient magnitude to obscure any signal produced by ionizing radiation. The solution is to reduce the background by cooling the detector to  $-196^{\circ}\text{C}$  with liquid nitrogen.

## IONIZING RADIATION: RISKS AND BENEFITS

Exposure to ionizing radiation from natural sources comes from radioisotopes found in the earth's crust and oceans, cosmic radiation from outer space and internal sources deposited when naturally occurring radioactive materials are inhaled or ingested. Exposure from these sources constitutes the total dose that most life on earth receives, and approximately half the annual dose to humans. The other half of what humans receive comes primarily from medical diagnostic tests and therapeutic applications of radiation used for curative or palliative procedures. Some populations of humans and other species have been exposed to radiation from nuclear bomb blasts during war time and during tests conducted in peace time, and as a consequence of nuclear power plant accidents.

Radiation exposure carries with it both risk and benefit, and although the objective is to maximize benefit while minimizing risk, this is not necessarily easy to achieve. For example, a medical diagnostic procedure such as mammography requires exposure to radiation, but can be essential for catching breast cancer in its early stages when it can be effectively treated and a cure more likely achieved. On the other hand, radiation exposure at high enough levels increases the risk of developing latent effects such as cancer that appear months or years later. Although an annual mammogram does not result in a dose of radiation that is associated with an increased risk of developing cancer, multiple exposures of the chest area as a consequence of several diagnostic procedures prescribed during the course of a year could measurably increase the risk of developing latent effects. Following the bombings of Hiroshima and Nagasaki the incidence of leukemia did not peak for 5–7 years, and following the Chernobyl disaster the appearance of thyroid cancer reached a maximum 6–7 years after the accident. Generally, lower doses of radiation are associated with longer latency in the appearance of latent effects.

### Mechanisms of injury and their consequences

The minimum energy needed for a single ionization event is 6–10 eV. Thus 1 MeV of radiation has the

potential to produce about 150,000 ionizations. As discussed, above electromagnetic radiations, including gamma rays and X-rays, have a relatively low LET, hence the reason for assigning them a  $w_R$  value of one. The penetration of electromagnetic radiation is given by the formula:

$$I(x) = I_0 e^{-\mu x}$$

where  $I_0$  and  $I(x)$  are the initial intensity and intensity at a distance  $x$  into the material, and  $\mu$  is the absorption coefficient of the material. The three types of interactions for electromagnetic radiation with matter described above contribute to  $\mu$  so that it can be rewritten as:

$$\mu = \mu_{\text{PE}} + \mu_{\text{C}} + \mu_{\text{P}}$$

where  $\mu_{\text{PE}}$ ,  $\mu_{\text{C}}$  and  $\mu_{\text{P}}$  are the respective contributions to the absorption coefficient by the photoelectric effect, Compton scattering and pair production. A derivation of the quantitative expression for each of these components is beyond the scope of this chapter, but the following relationships are informative:

$$\mu_{\text{PE}} \propto N(Z^5/E_{\gamma}^3)$$

where  $N$  is the number of absorber atoms per unit volume,  $Z$  is the atomic number of the absorber and  $E_{\gamma}$  is the energy of the radiation. Absorption due to the photoelectric effect increases sharply with atomic number making it an important factor in absorption by tissues like calcium-laden bone. There is also a precipitous decrease in absorption due to the photoelectric effect as energy of the radiation increases, indicating that the photoelectric effect is important in the absorption of lower energy radiation. The contribution of Compton scattering to the absorption coefficient is given by the proportionality:

$$\mu_{\text{C}} \propto NZ/E_{\gamma}$$

As with the photoelectric effect, absorption by Compton scattering varies directly with the atomic number of the absorber and inversely with the energy of the radiation. In contrast to the photoelectric effect, the relationships are linear not exponential. Consequently, scattered photons are more likely to escape absorption so as not to deposit all of their energy in the tissue. Absorption due to pair production is given by the approximation:

$$\mu_{\text{P}} \cong NZ^2(E_{\gamma} - 2m_0c^2)$$

Obviously absorption by pair production does not occur until  $E_{\gamma} = 2m_0c^2$  (1.02 MeV). For radiation with energy in excess of 1.02 MeV, absorption by this mechanism becomes important.

A radioactive substance that emits gamma rays is easy to detect if ingested because, as noted above, the radiation is most often not entirely absorbed by the body and can be detected externally with instruments. In contrast, radioactive materials such as Sr-90 and Pu-239, isotopes that would be released in a nuclear power plant accident or by the detonation of nuclear weapons, emit only alpha and beta particles. They have a high LET and deposit all of their energy within millimeters or centimeters of their source. Consequently, if inhaled or ingested they do not escape the body making them difficult to detect. When evaluating the health effects of ingested or inhaled radioisotopes, the biological half-life ( $t_b$ ), the time needed to excrete half the radioactive material from the body, is an important consideration. Values of  $t_b$  vary with species, age and the isotope taken in. For example, Cs-137 released in the Chernobyl accident was found in the bodies of humans and sheep. Even though it has a  $t_{1/2}$  of 30 years, its  $t_b$  was 3 months in humans and only 2–3 weeks in sheep. Since the  $t_b$  is relatively short in sheep, it is not unreasonable to “feed down” the animals before slaughter to bring the radioactive content of the meat to a level that does not present a health risk when consumed. Including some agents such as Berlin blue in the feed can also reduce the  $t_b$ . Using non-radioactive isotopes to compete with a radioisotope can also be effective in reducing the  $t_b$  or as a prophylaxis in advance of a potential exposure. For example, taking non-radioactive I-130 will compete with the radioisotope I-131 for uptake by the thyroid, thus protecting it from damage by the latter. For radioisotopes such as radium and strontium, which are deposited in bone and remain there indefinitely, the  $t_b$  is equal to the  $t_{1/2}$ . Radioisotopes also have what is known as a radio-ecological  $t_{1/2}$  defined as the half-life for the animals and plants living in a particular area. Radio-ecological  $t_{1/2}$  may be difficult to determine and the disappearance of radioactivity from the environment may not follow an exponential decay curve classically described by a half-life equation.

Death due to radiation that occurs within 30 days of exposure is known as acute radiation death. The doses that will cause acute radiation death in half of the exposed population (the LD<sub>50</sub>) for different species are given in Table 25.6 (Henriksen and Maillie, 2003). The pathological effects of radiation depend upon the dose that is received. Rapidly growing cells, such as cancer cells, intestinal epithelial cells and hematopoietic cells, are more susceptible to high doses of radiation than are quiescent cells. For humans, a dose of 3–10 Gy causes hematopoietic syndrome, which results from damage to the bone marrow and destroys the body’s ability to produce erythrocytes and cells of the immune system. The victim experiences nausea, vomiting, and diarrhea, and without the ability to fight infection, death occurs within a few weeks. Gastrointestinal syndrome results from a

TABLE 25.6 Acute doses of radiation that result in 50% lethality (LD<sub>50</sub>) of an exposed population

Organism	LD <sub>50</sub> dose in Gy
Human	3–5
Dog	3.5
Monkey	6
Frog	7
Rat	7.5
Rabbit	8
Tortoise	15
Goldfish	23
Bacteria	>1000

dose of 10–100 Gy in which the cells of the intestinal epithelium are destroyed as is the ability to produce blood cells. The victim experiences stomach and intestinal pain, nausea, vomiting and diarrhea with death occurring within 3–10 days in dogs (Hanford, 1960) and humans. Doses greater than 100 Gy cause central nervous system syndrome that manifests as irritability, hyperactive response, fatigue, vomiting, diarrhea, loss of coordination, shivering, coma and death within 48 hours.

The greatest number of war-related acute radiation syndrome deaths occurred in the bombing of Hiroshima and Nagasaki in 1945, and the majority of acute radiation syndrome deaths caused by accidents occurred at Chernobyl. There is only one confirmed case in which a radioactive material has been used successfully to assassinate someone. Alexander Litvinenko, a former officer in the Russian Federal Security Service, escaped prosecution in Russia and received political asylum in the United Kingdom. As the author of *Blowing up Russia: Terror from Within* and *Lubyanka Criminal Group*, he accused the Russian secret service of carrying out acts of terrorism to bring Vladimir Putin to power. On November 1, 2006, Litvinenko suddenly fell ill and was hospitalized. He died 3 weeks later, the victim of lethal polonium-210-induced acute radiation syndrome. This set off an investigation that led to a diplomatic rift between the British and Russian governments. British officials had identified a former officer of the Russian Federal Protective Services, Andrei Lugovoy, as the primary suspect. Unsuccessful attempts were made to have him extradited to Britain and subsequent election to the Duma secured his immunity from prosecution.

By and large, acute radiation syndrome does not represent a serious health issue simply because it so rarely happens and is generally preventable. On the other hand, latent effects caused by much lower doses of radiation than those responsible for acute radiation syndrome need to be considered with regard to health policies. Any of the macromolecules that go into the making of a cell including proteins that are encoded by approximately 30,000 human genes together with the lipids and

carbohydrates that these proteins are often responsible for metabolizing can be damaged by radiation. At the high doses of radiation that cause acute radiation death, the damage is so severe that the cell cannot recover, and consequently dies as a result of the initial insult or because the cell becomes apoptotic which in essence, means that it commits suicide. There are hundreds or thousands or millions of copies of each of these macromolecules, and as long as the genes that encode the proteins are not irreparably damaged, new proteins can be made to replace those that are no longer functional. If the dose of radiation is less than 4–5 Gy, it is likely that the most sensitive cells in bone marrow and the gastrointestinal tract will recover and the victim will live. In these cases, it is latent effects, primarily the appearance of cancer, that become a health issue. The event that gives rise to these effects is usually damage to the genetic material, the DNA, of the cell. DNA is made up of two helical strands each consisting of a backbone of alternating sugar and phosphate molecules with purine (adenine or guanine) or pyrimidine (cytosine or thymine) bases attached to the sugar moieties. The bases on each strand form non-covalent-bonded base pairs with each other (guanine paired with cytosine and adenine paired with thymine) that knit the two DNA backbones together. Unlike the other macromolecules in the cell, there are most often only two copies of the gene that encode a particular protein. Many proteins are enzymes that function as catalysts in metabolic pathways within the cell. Some of these are enzymes that ensure the fidelity of DNA replication and repair damaged DNA. Endonucleases and exonucleases remove mismatched or damaged bases, polymerases replace them and ligases ensure that there are no nicks in the DNA backbone. Damage occurs when radiation causes breaks in the DNA. A break in the backbone of one strand is quickly repaired. Multiple breaks can also occur sometimes in close proximity and on opposite DNA strands. Such breaks are associated with cell death in prokaryotic bacteria. In eukaryotes, the damage can be repaired, but not as easily as a single strand break. If genes that encode DNA repair enzymes are damaged and the damage is not repaired the result could be mutations that alter or destroy the activity of the enzymes. If the ability of the cell to repair DNA damage is compromised, additional mutations may occur. Furthermore, there are proteins that act to stop the uncontrolled growth of a cell by triggering apoptosis and killing the cell rather than allowing it to become cancerous. In cells lacking an intact DNA repair machinery, damage of the DNA that codes for these critical proteins cannot be effectively repaired and the encoded proteins may not be functional, resulting in an increased risk of the cell becoming cancerous. Consider the following example. Ultraviolet radiation can cause the covalent linkage of adjacent pyrimidine bases (cytosine or

thymine) generating pyrimidine dimers. Normally the damage can be repaired by the cell, but individuals with a genetic disorder known as xeroderma pigmentosum have mutations in some of the DNA repair proteins and enzymes that compromise or destroy their activity. These individuals are predisposed to developing skin cancer that is often lethal.

Radiation damage to DNA or more correctly to chromatin (a complex of DNA and proteins) can be observed at the microscopic level. Cells go through a series of phases known as the cell cycle in the process of dividing. During metaphase, the chromatin is compacted so that the chromosomes can be seen under a light microscope. The chromosome consists of a pair of chromatids that are equal in length and joined by a single centromere in such a way that each chromatid has a long arm and a short arm. Radiation can generate chromosomal aberrations in the form of rings (ring formation) or the presence of two centromeres (dicentric). The percentage of cells with chromosomal aberrations increases with the dose of radiation, and can be used as a biological dosimeter for exposures of 0.2 to 12 Gy.

## Natural sources

Cosmic radiation and naturally occurring radioactive materials in the earth's atmosphere, the earth's crust and in its oceans constitute the natural sources of radiation that all organisms are exposed to. About 85–89% of incoming cosmic ray nuclei are protons (hydrogen nuclei), 10–13% are alpha particles and 1% of cosmic ray nuclei are those of the heavier elements. These nuclei together make up 99% of cosmic rays, and electrons (which cannot be distinguished from beta particles because their source, whether it be atomic nuclei or extra nuclear, is not known) constitute the remaining 1% of the particles that make up galactic cosmic rays. Earlier, it was stated that alpha particles with energies in the range of 3–7 MeV only travel a few centimeters in air, so how is it that they can reach the earth's surface from outer space? The reason is that the particles in cosmic rays reach the earth with energies on the order of  $10^{14}$  MeV. The earth's atmosphere acts as a partial shield against cosmic rays, and as you travel away from the earth's surface, for example when flying on an airplane or living at higher elevations, there is an increase in the absorbed dose during that period of time. On a typical airplane flight, the dose rate from cosmic radiation at cruising altitude is approximately 40 to 100 times that at sea level.

The other source of natural radiation comes from radioisotopes that were incorporated into the earth's crust when it was formed. The most important elements in this regard are uranium-238 and thorium-232 and the radioisotopes that result from their decay (their radioactive

**TABLE 25.7** Typical doses of radiation received from natural environmental sources

Source	Annual dose in mSv
Cosmic radiation (airline crew)	3–5
Cosmic radiation (exposure at sea level)	0.3–0.6
Natural gamma radiation	0.5
Buildings	0.9–1.3
Food	0.3–0.4

families), and potassium-40. These radioisotopes are not evenly distributed over the earth's surface. Consequently, the dose of radiation received will vary depending upon locality. Being inside a building does not necessarily offer protection from radiation because the construction materials used in making the building will contain radioisotopes. The use of shale in the construction of homes in Sweden was banned in 1979 because it had unacceptably high levels of uranium. Homes made of red brick often have higher levels of radiation contributed by K-40. Depending upon the construction materials and the place of their origin, the dose received from a building can vary by a factor of about two.

Exposure to radiation also comes from food with the principal contributor being K-40 and C-14. K-40 with a  $t_{1/2}$  of  $1.25 \times 10^9$  years accounts for about half of the dose due to internal sources, contributing 40–70 Bq/kg body weight depending upon sex and age. Carbon makes up the other half contributing about 50 Bq/kg and there are traces of 3-H that contribute less than 1 Bq/kg. A summary of the contribution that various natural sources give to the total annual absorbed dose is provided in Table 25.7. It is enlightening to realize that the average background exposure to natural radiation causes approximately  $5 \times 10^8$  ionizations per second in humans with average body mass. The rate is proportional to the target size so, if you happen to be a sumo wrestler your body may be subjected to a billion ionizations per second.

## Nuclear weapons

There have been more than 2000 nuclear weapons detonated since 1945 and 461 of these have been in the atmosphere. Most atmospheric testing ceased in 1963 with the exception of France where atmospheric tests continued until 1974 and China where they continued until 1980. Explosions near ground level draw dirt and debris into the mushroom cloud creating large amounts of radioactive fallout. Despite atmospheric testing, the radiation received by the average individual worldwide is not increased measurably over background, and barring future tests or the use of nuclear weapons in war this will not change. Obviously, there are populations

that have received high doses of radiation from nuclear explosions. The combined death toll in Hiroshima and Nagasaki was estimated to be 103,000. The majority, approximately 67,000, were killed in the initial blast and 36,000 in the 4 months following the attacks. It is not known how many in the latter group died as the result of acute radiation syndrome. The estimated average dose of radiation to those that were exposed was 160 mSv. During nuclear tests, efforts are made to protect humans from exposure to radiation, but a test detonation by the United States in the Bikini atoll in 1954 exposed the crew of 23 men aboard the Japanese tuna fishing boat *Daigo Fukury Maru* to an estimated 2–6 Sv of radiation. When examined in 1982, these men had an increased number of chromosomal aberrations in their lymphocytes as did survivors of the nuclear bombs dropped on Hiroshima and Nagasaki.

## Nuclear power
